To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate

the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Future Challenges of Sea Level Rise and Climate Change

Global observations from satellites and long-term data collection have made it possible to document and analyze patterns in the Earth's climate. Scientific analysis of the impact of these changes has helped to improve the understanding of future flood hazard driving forces and long-term impacts on human activities and watershed master planning (http://www.research.noaa.gov/climate/t_observing.html). Examples of impacts are rising global average air and ocean temperatures, increased and earlier snow and ice melt, shorter subtropical rainy seasons, shifted seasons, sea level rise and greater variations in temperature and precipitation (IPCC, 2013; Freas et al., 2008; Marshall et al., 2004; Bloetscher et al., 2010). Marshall et al. (2004) specifically focused on the Florida peninsula to predict changes in rainfall and warmer temperatures but interspersed lower low temperatures due to the potential loss of wetlands.

Future changes in climate will add to the existing impacts, at a time when the population of the state is expected to nearly double by 2030. Additional research and high-resolution climate modeling for the Florida peninsula and local jurisdictions is needed to help guide long-term plans like WMPs. Rainfall appears to be decreasing and temperatures rising (see **Error! Reference source not found.**).

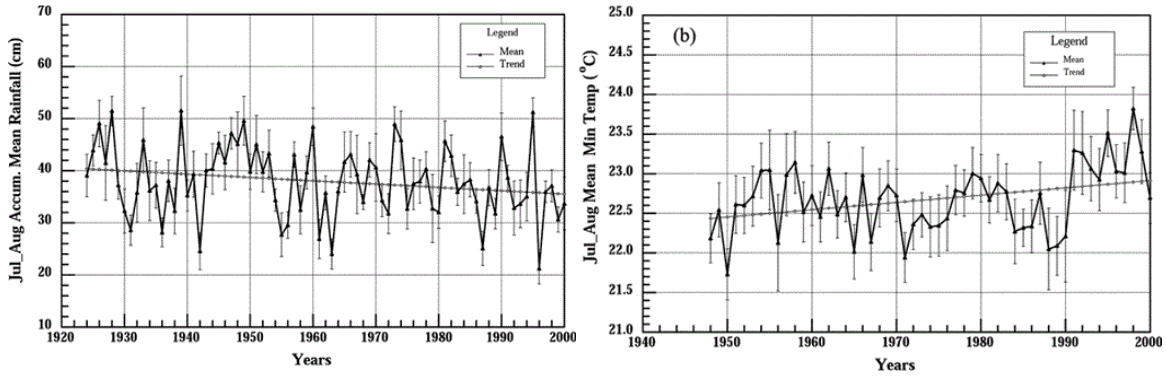

Figure 31. Change in average rainfall and change in average temp 1924 to 2000. Note the reversed trend, which means groundwater input variability is lessened. Source: Marshall et al., 2004.

Climate change is likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as

sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly compromised stormwater drainage systems, and d) more frequent inundation of barrier islands and coastal areas.

NOAA and IPCC (2013) predictions suggest that by 2100, global temperatures will be on the order of 2-3°C (3-5°F) higher and sea levels will rise by up to 3 feet. Accompanying these drivers are potential changes in storm frequency and intensity, desertification, population migration, ocean acidification and coastal flooding (IPCC, 2007), exacerbated by the land cover and land use changes, which are substantially impacted by the fluxes, timing and quality of precipitation (Adrians et al., 2003; Scanlon et al., 2005; Marshall et al., 2004; Salmun and Molod, 2006), and leading to changes in the timing of peak flows and volumes (Richey and Costa-Cabral, 2006).

The results of these climatic changes are likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly An outcome of these climatic patterns is that during the past 140 years, an increase in sea levels has been observed (Bloetscher, 2012), a worrying pattern since sea level rise is a permanent phenomenon, that can be catastrophic to low lying areas in the long-term. The question is how much and how soon? Various studies (Bindoff et al., 2007; Domingues et al., 2008; Edwards, 2007; Gregory, 2008; Vermeer and Rahmstorf, 2009; Jevrejeva, Moore and Grinsted, 2010; Bloetscher, 2010, 2011; IPCC, 2007; Heimlich et al., 2009) indicate large uncertainty in projections of sea level rise by 2100. Gregory et al. (2012) note that during the last two decades, the global rate of sea level rise has been larger than the 20th-century time-mean, and Church et al. (2011) suggested that the cause was increased rates of thermal expansion, glacier mass loss, and ice discharge from icesheets. Gregory et al. (2012) suggested that there may also be increasing contributions to global sea level rise from the effects of groundwater depletion, reservoir impoundment, and loss of storage capacity in surface waters due to siltation. Measurements of Florida's east coast (Maul, 2008) show an average rate of sea level rise of 2.27 ± 0.04 mm per year from 1915 to 1992 based on tide gauge readings. Analyzing the tidal gauge readings for Florida shows that:

1. Florida average sea level rise is 2.10 ± 0.49 mm/yr
2. All but one location is within the 95% confidence limit range (the exception is Panama City where there is evidence of submergence and other land-based issues)

3. None of the Florida sea level rise rates differ statistically
4. Average global sea level rise for 1920-2000 was 2.0 mm/yr – within 95% confidence limit for Florida locations

From 1929 to 1992, over eight inches of sea, with another 6 inches added since 1992, which is already having significant impacts on coastal communities where population growth has increased the need for improved flood management strategies (Bloetscher, 2008; Parkinson, 2010; Zhang et al., 2011, 2011a; NFIP, 2011; Schmidt et al., 2011; Warner et al., 2012).

As a result, the SFRCCC (2015) adopted USACE's methodology to derive scenarios of sea level change intermediate to high rates of sea level rise for years 2030 (3" to 7") and 2060 (9" to 24") as the consensus projection to guide future planning. The path keeps increasing – now 14 inches since 1929 (**Error! Reference source not found.**) caused by thermal expansion of the ocean and melting ice caps (Jevrejeva et al., 2010; Vermeer and Rahmstorf, 2009). Sea level rise is a major concern in Florida, including Walton County, since the majority of the state's population live on the coast, involving most major commercial, residential, and economic enterprises. **Error! Reference source not found.** demonstrate the estimated sea level change for Panama City, considering the predictions of NOAA 2017. For NOAA high scenario SLR change scenario, the estimated level change is higher than 8 ft., while for the intermediate and low scenarios are about 3.9 feet and 1.7 feet respectively.

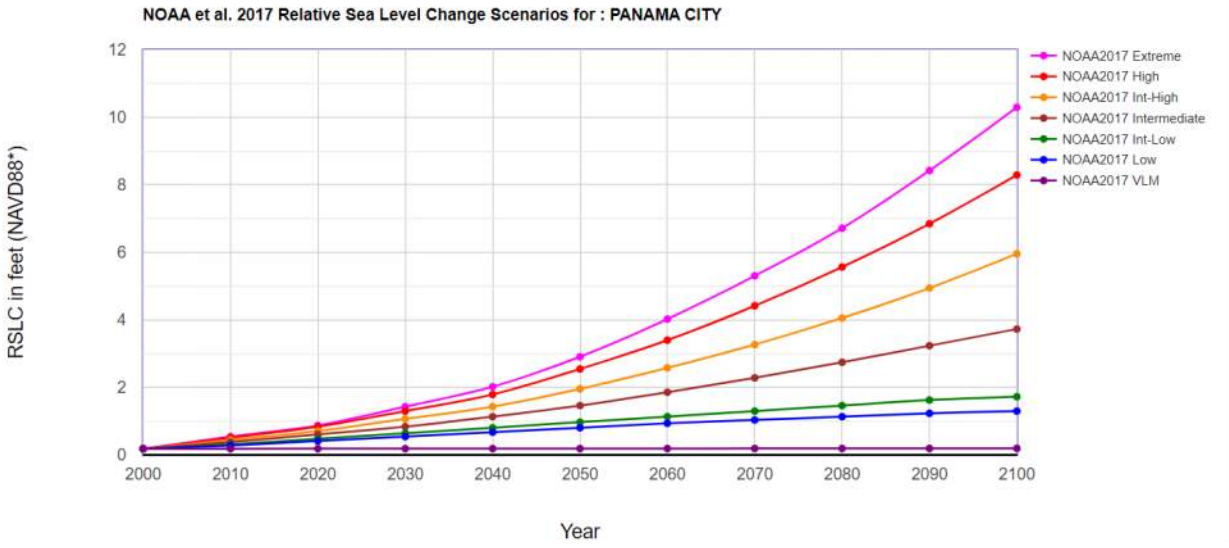

Figure 32. Relative Sea Level Change Scenarios for gauge 8729108, Panama City, FL. Source: NOAA 2017 (https://cwbi-app.sec.usace.army.mil/rccslc/slcc_calc.html).

NOAA (2017) outlines five scenarios for sea level rise. The NFIP proposes the use of the intermediate high projection, which is 1.2 meters or 4 ft globally from current sea level elevations (**Error! Reference source not found.**).

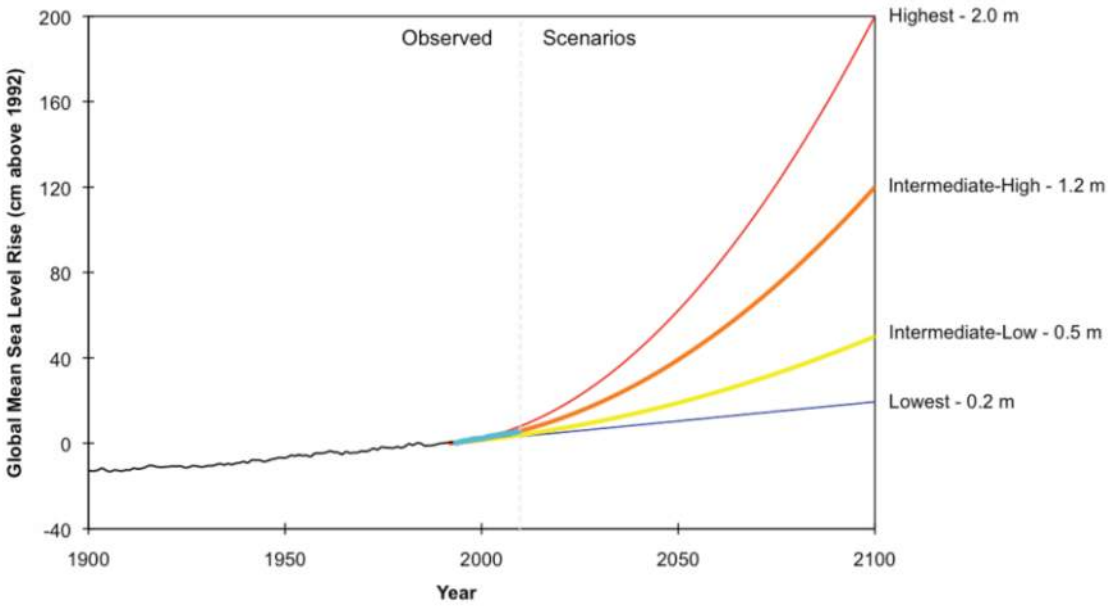

Figure 33. Graphic of global sea level rise projections from NOAA (2017). Source:https://tidesandcurrents.noaa.gov/publications/techrpt83_Global_and_Regional_SLR_Scenarios_for_the_US_final.pdf

As sea level rises, access to roads, bridges, rail, and transit could be at risk of flooding, causing the effects of sea level rise to spread indirectly throughout the entire transportation network, affecting the overall system performance. For example, the flooding of a critical road or facility access can cause a shifting of traffic flow causing congested conditions in other roadways that are not actually flooded. Since the roadway network would be unable to carry the traffic demand, the system would experience operational failure; as a result, causing travel times and delays. Moreover, the inundation of a critical access could cause transportation connectivity problems to essential infrastructure like ports or airports. Transportation infrastructure relies on the effectiveness of flood control and stormwater drainage systems for the transportation corridors. Road integrity relies on adequate drainage. The increased risk of severe flooding in Florida's low-lying terrain can adversely affect transportation infrastructure along the coastline; roads can be inundated, and roadway beds can be damaged. Sea level rise will cause increased water table levels (FDOT, 2012), as regional water tables cannot exist naturally below mean high tide (2 feet in Florida). Adding 3 feet of sea level rise on top of groundwater would compound the risk of flooding in low-lying areas. Road bases below 5 feet NVGD would become saturated under this scenario, likely causing premature base failure. As soil storage capacity is diminished due to rising groundwater elevations associated with sea level rise, the potential for more frequently flooded roadways would likely damage pavements (FDOT, 2012). Hence sea level rise must be accounted for in WMPs in coastal areas. To allow flexibility in the analysis due to the range of increases within the different time periods, an approach that uses incremental increases of 1, 2, and 3 feet of sea level rise is suggested for modeling. The increments can work as threshold values in planning

considerations in terms of allowing planners the ability to know ahead of time where the next set of vulnerable areas will be, to allow for a proactive response approach that can be matched to the observed future rates. Sea level rise is a major concern since nearly half the US population lives within 50 miles of the coast, involving most major commercial, residential, and economic enterprises. The effects of 5 ft sea level rise, King tide, and 1-day 100-year storm event are shown in **Error! Reference source not found.**.

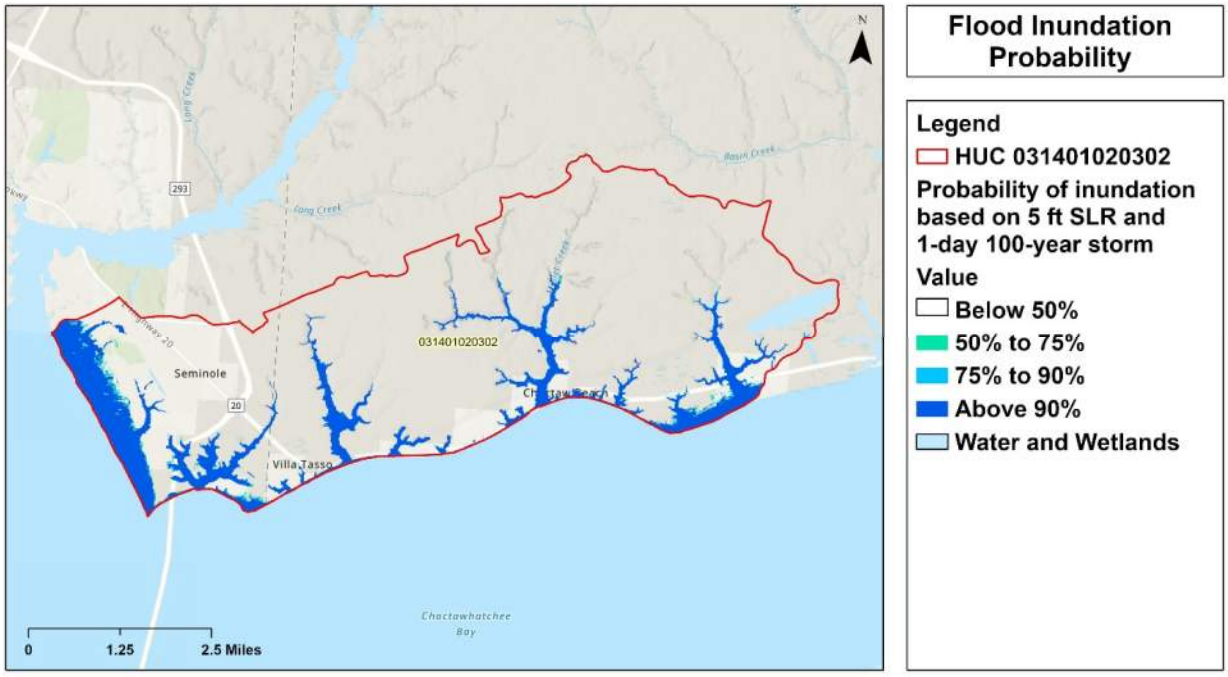

Figure 34. Flood Inundation Probability for a Sea level rise of 5 ft + 1-day 100-year storm event for HUC 031401020302 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Dark blue is area under 5 ft NAVD88 and potentially inundated at the 99th percentile tidal conditions. Processed by FAU.

2.4 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. **3-day 25-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 35)
2. **1-day 100-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 36)

3. **1-day 10-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 37)
4. **1-day 5-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 38)
5. **Sea level rise of 1 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 39)
6. **Sea level rise of 1 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations storm (Figure 40)
7. **Sea level rise of 1 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 41)
8. **Sea level rise of 1 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 42)
9. **Sea level rise of 2 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 43)
10. **Sea level rise of 2 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 44)
11. **Sea level rise of 2 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 45)
12. **Sea level rise of 2 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 46)
13. **Sea level rise of 3 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 47)
14. **Sea level rise of 3 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 48)
15. **Sea level rise of 3 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 49)
16. **Sea level rise of 3 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 50)

17. **Sea level rise of 4 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 51)
18. **Sea level rise of 4 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 52)
19. **Sea level rise of 4 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 53)
20. **Sea level rise of 4 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 54)
21. **Sea level rise of 5 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 55)
22. **Sea level rise of 5 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 56)
23. **Sea level rise of 5 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 57)
24. **Sea level rise of 5 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 58)

In all scenarios, a considerable amount of flooding is noted along the coast and following the waterbodies flow path. As this basin connects to the ocean though Choctawhatchee Bay, SLR scenarios plays an important hole, implying a considered growth as the projected scenario of rising tides rises.

The design storm simulation determined that approximately 5.5% of the HUC total area or 1.46 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 6% of the HUC's total area, or 1.60 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 5% of the HUC's total area, or 1.32 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 4.7% of the HUC's total area, or 1.25 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401020302 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	25.19	1.46	94.5%	5.5%
1-day 100-year	25.05	1.60	94.0%	6.0%
1-day 10-year	25.32	1.32	95.0%	5.0%
1-day 5-year	25.40	1.25	95.3%	4.7%

2.5 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6
1	Single Family Residential	5

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.5.1 Results

Error! Reference source not found. to **Error! Reference source not found.** depict the HUC 031401020302 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 60) overlays critical facilities onto the 1-day 100-year storm event scenario, while the third map (**Error! Reference source not found.**) represents the same overlay within the context of 5 feet of sea level rise (SLR) combined with the 1-day 100-year storm event. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 5 feet SLR + 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** and **Error! Reference source not found.** illustrate the composite score for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. **Error! Reference source not found.** represents the calculation for composite score based on 1-day 100-year storm event, while **Error! Reference source not found.** shows the calculation for composite score for the same storm event, but including a 5 feet of Sea Level Rise scenario. **Error! Reference source not found.** shows the same area zoomed out.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.5.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020302. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.5.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020302. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020302	17056.82
All of the 1-day 100-year storm event inundation	**1023.41**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	287.56
B. Federal Land in 1-day 100-year inundation > 10 acres	329.39
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	406.46
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	406.46

2.5.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not**

found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

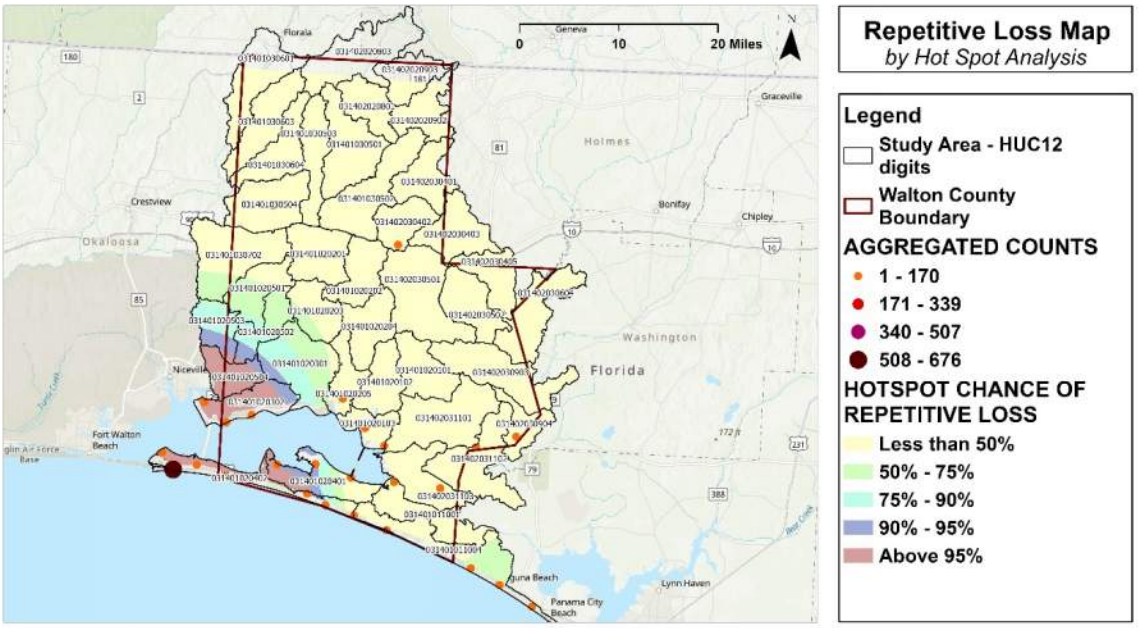

Figure 66. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.5.5 Priority Projects

The basin has a significant amount of developed land, since encompass the communities of Seminole (outside Walton County boundary), Villa Tasso, and Choctaw Beach. Unfortunately, a substantial portion of these communities faces the risk of flooding, particularly in the event of a 1-day 100-year storm event + 5 ft. SRL scenario.

In terms of priority for land use, there are five critical facilities (tier 1) within the basin, although none of them are situated within the flood zone. There is also a considerable number of parcels, specifically 123, categorized as tier 2. Among these, four are supermarkets, four are financial institutions, three are private schools, and the remainder consists of roads, with a notable portion of them being within the flood zone.

Furthermore, the basin includes 137 parcels categorized as tier 3, 275 as tier 4, and over 4,800 as tier 5. A substantial number of these parcels are within the flood zone.

When examining the composite score, seven parcels fall within the score range of 5-6, representing the highest priority for intervention. Notably, all of these parcels are roads, including Indian Cv, County Park, Restabit Ln, Bay Shore Dr, Nimrod Cir, Restabit Ln, and Cedar Beach Cv. Additionally, there are 37 parcels with a score of 4-5, which includes one office building, with the

rest being roads such as County Park, Crestview St, Streets, Restabit Ln, County Line Rd, Marina Ct, Magnolia St, Eastern Street, and Hudson Dr.

In the score range of 3-4, there are 13 parcels, encompassing three light manufacturing facilities and ten mobile homes. Finally, there are 16 parcels with a score below 3, all of which are mobile homes.

More detail about flood solutions are described in the community plan and in Section 5.5 where drilldown to specific neighborhoods is outlined.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 sub-watershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub- watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020401) is highlighted among all the HUCs to help identifying its location. (Figure 3).

Santa Rosa Beach, a coastal community in Walton County, is within the HUC 031401020401 boundary. Demographics data and other considerations of Santa Rosa Beach, along with other cities and communities in Walton County, will be covered in subsequent discussions.

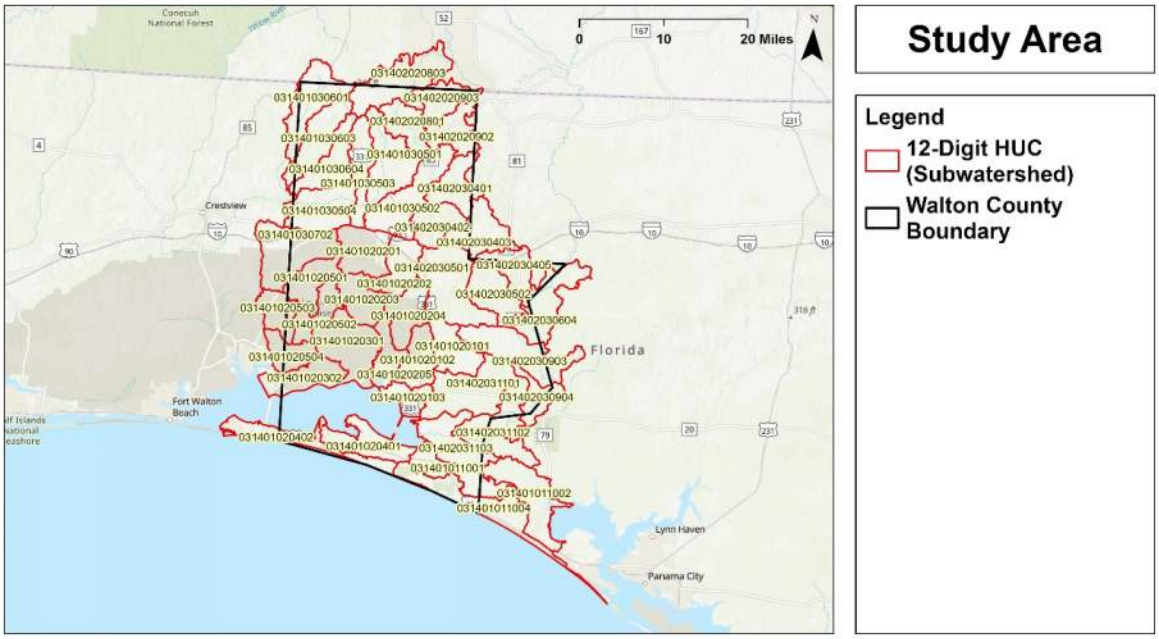

Figure 1. Walton County and all HUCs 12-digit sub-watershed, processed by FAU.

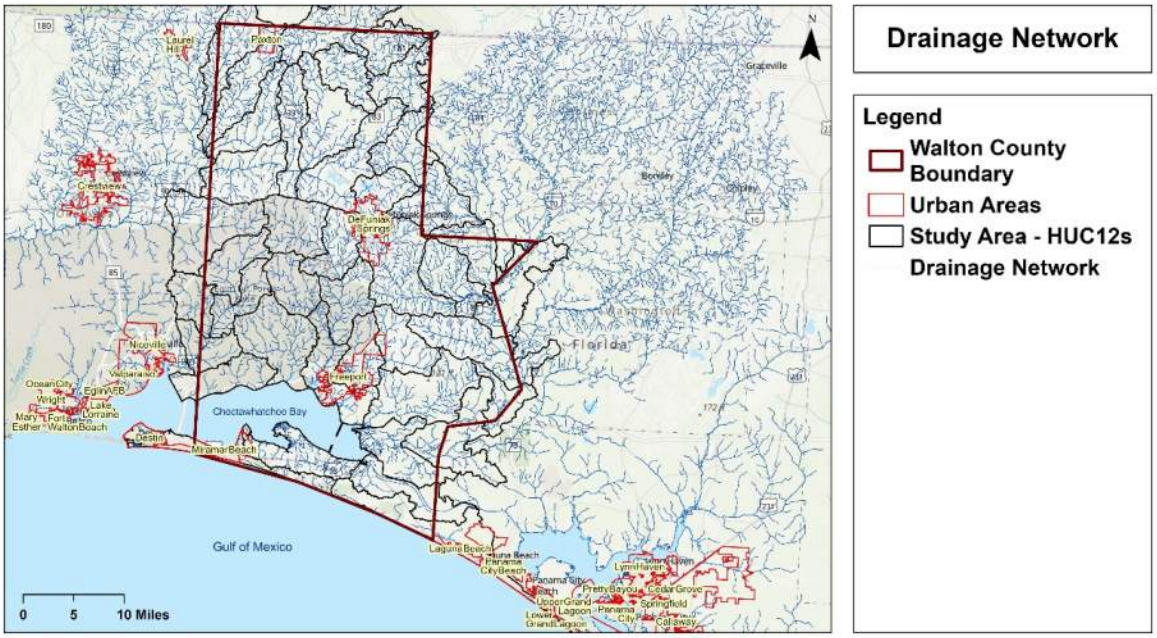

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

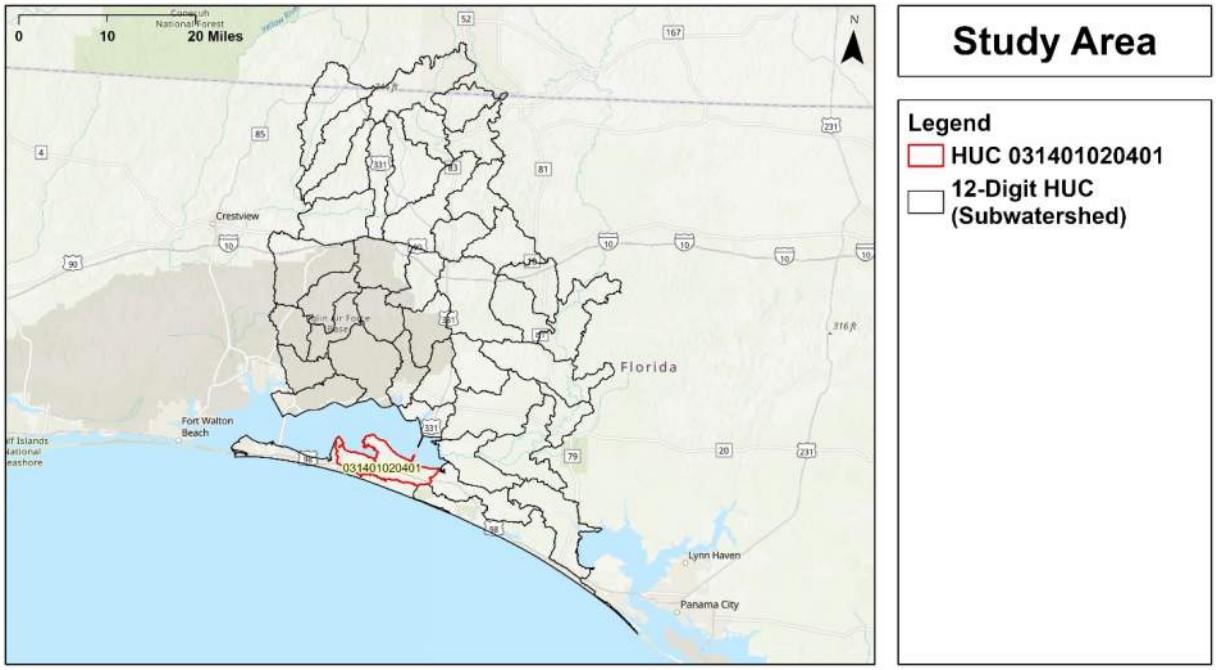

Figure 3. HUC 031401020401 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse

demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in Table 2.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In

order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (Figure 4). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

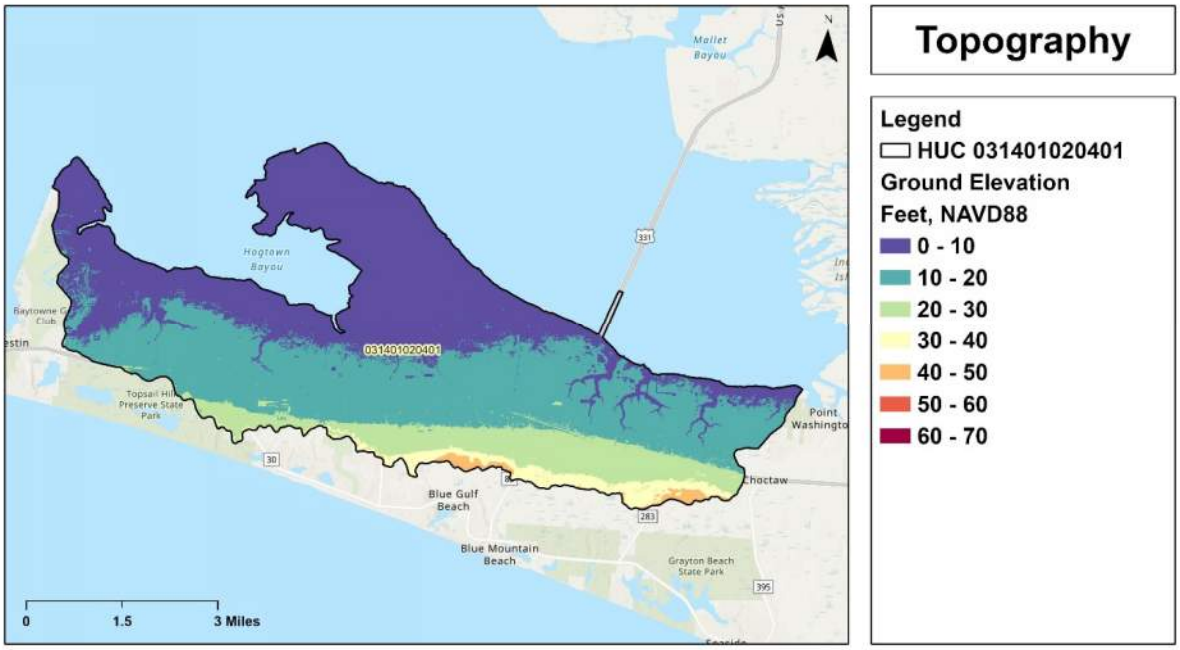

Figure 4. Topographic map of the HUC 031401020401 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020401 sub-watershed is shown in **Error! Reference source not found.**.

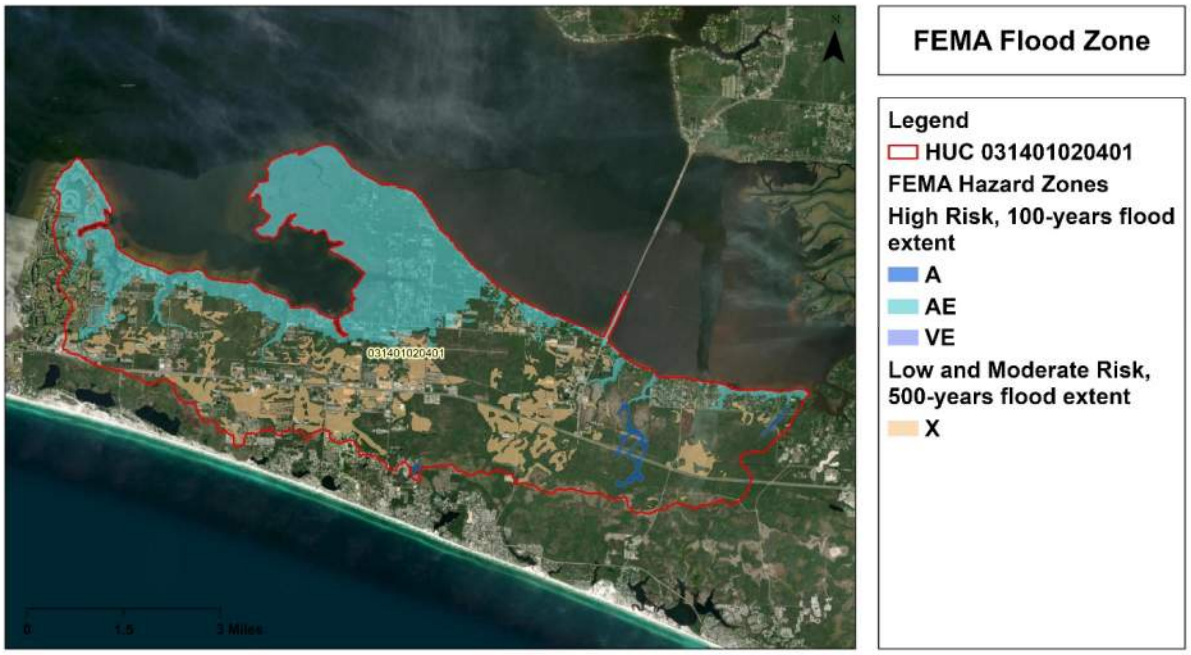

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020401 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401020401 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall

biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

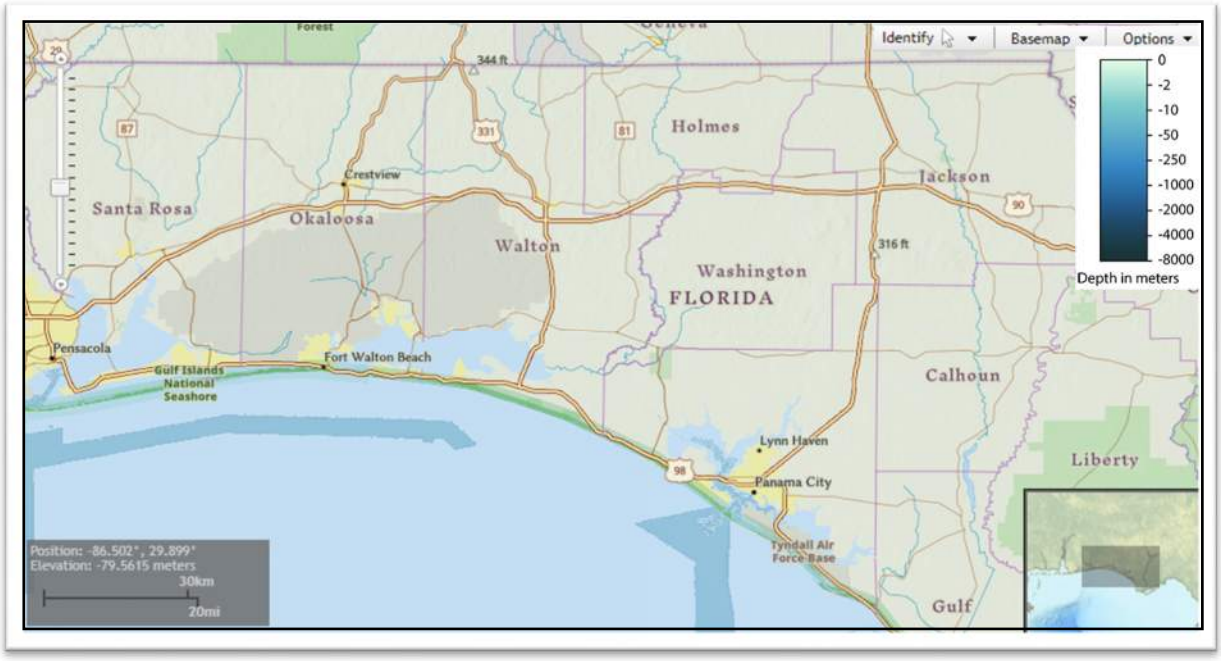

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

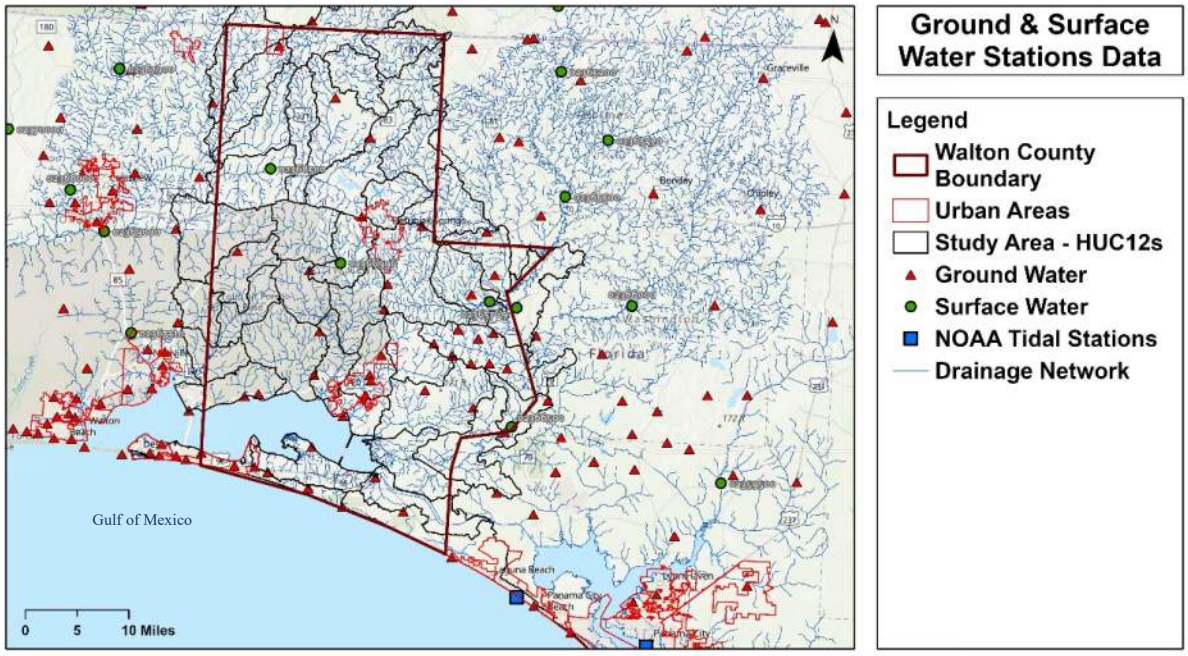

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The major water bodies in the sub-watershed are the Choctawhatchee Bay and Hogtown Bayou, with the associated rivers and canals:

- Mack Bayou
- Buck Bayou
- Hewett Bayou

- Mussett Bayou
- Bowman Bayou
- Littles Bayou
- McQuage Bayou

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401020401, which is USGS 02366500 Choctawhatchee River NR Bruce FLA.

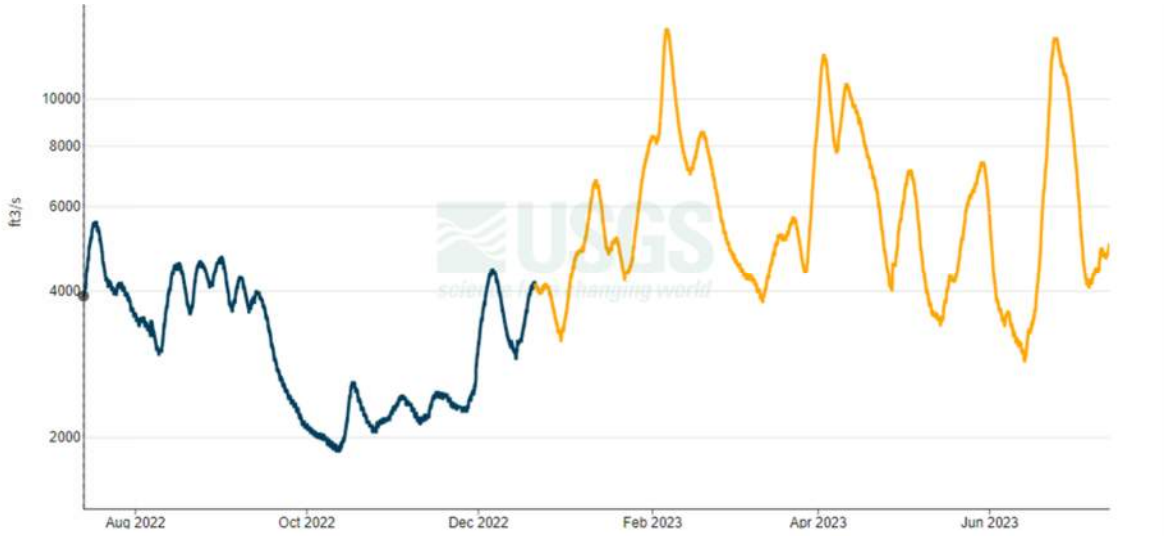

Figure 8. Average streamflow for Choctawhatchee River NR Bruce FLA (USGS 02366500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366500/#parameterCode=00065&period=P365D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific

mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Figure 9 shows the drainage network of HUC 031401020401 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020401 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

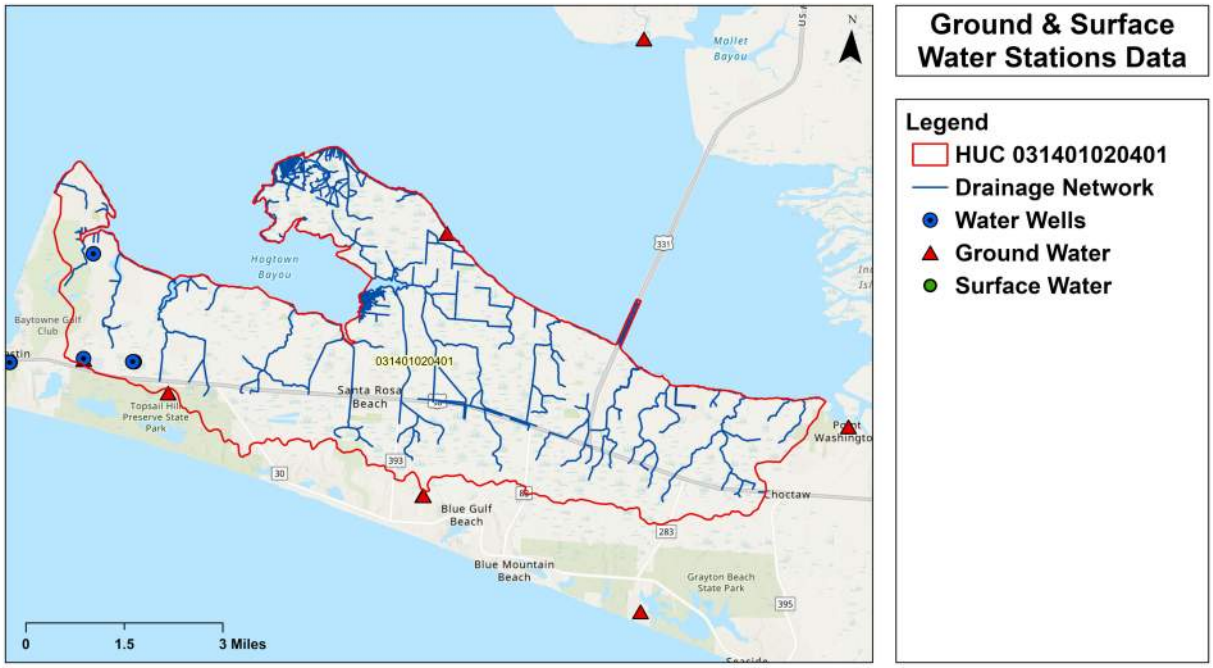

Figure 9. Ground and Surface Water Stations in the HUC 031401020401 sub-watershed, processed by FAU.

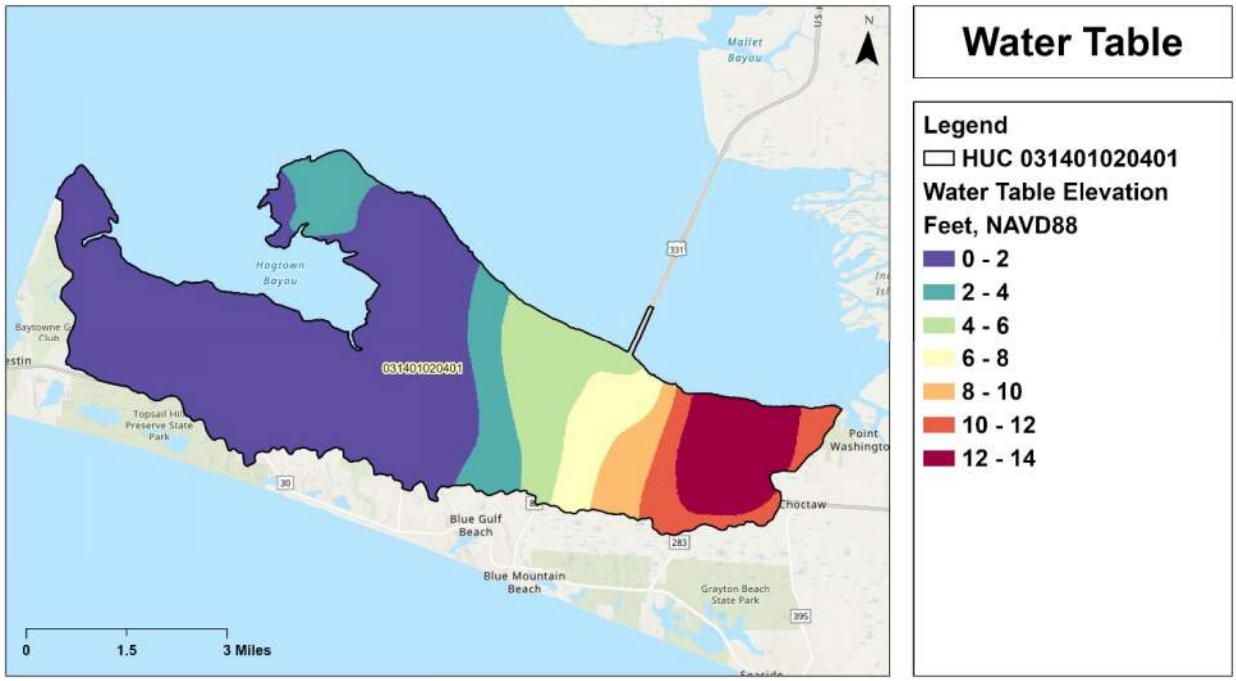

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020401 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

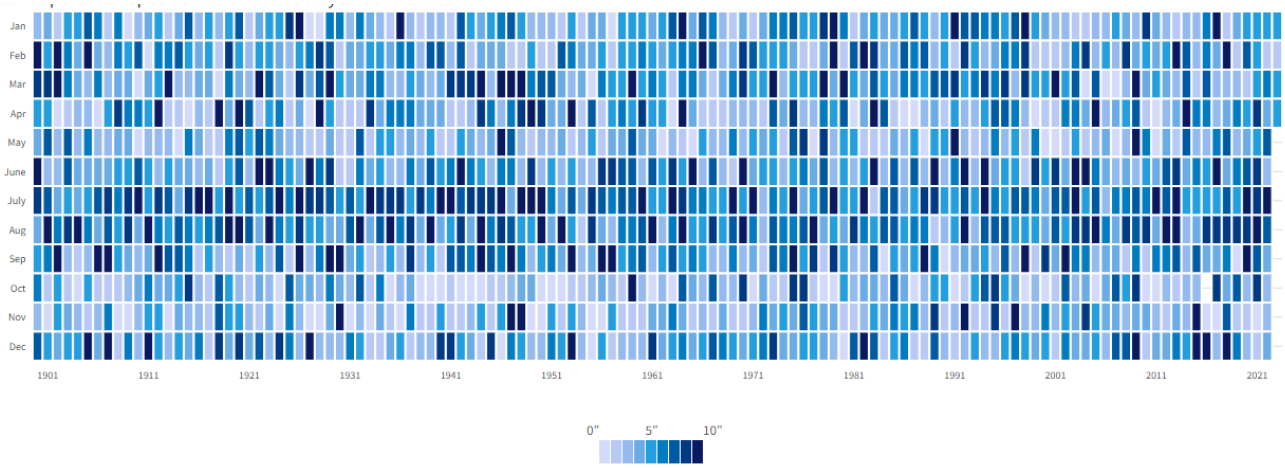

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

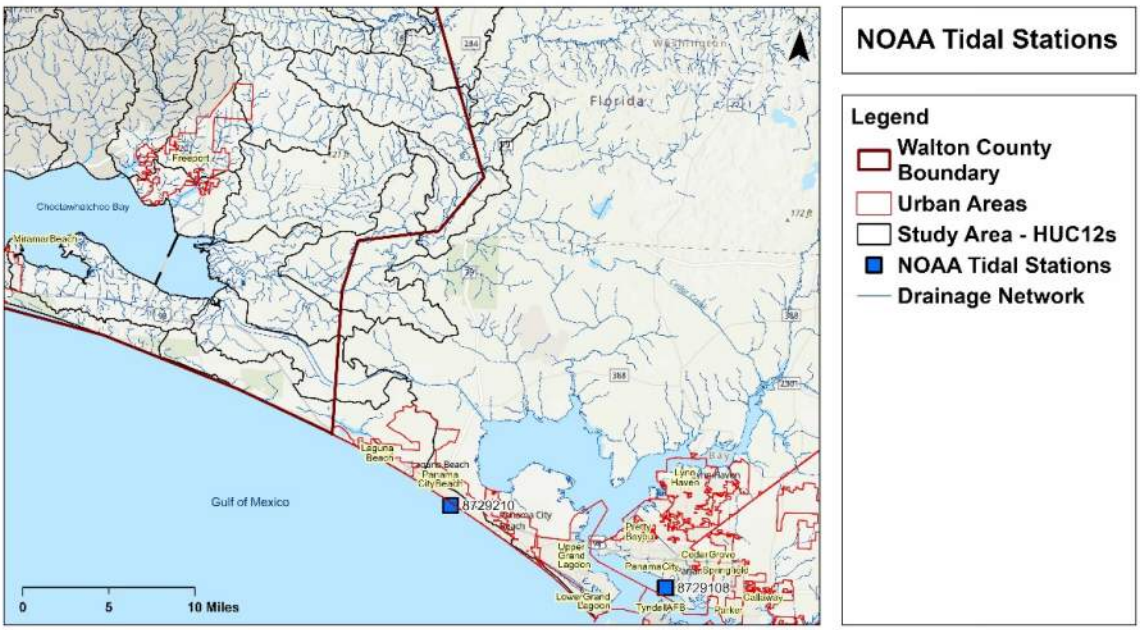

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

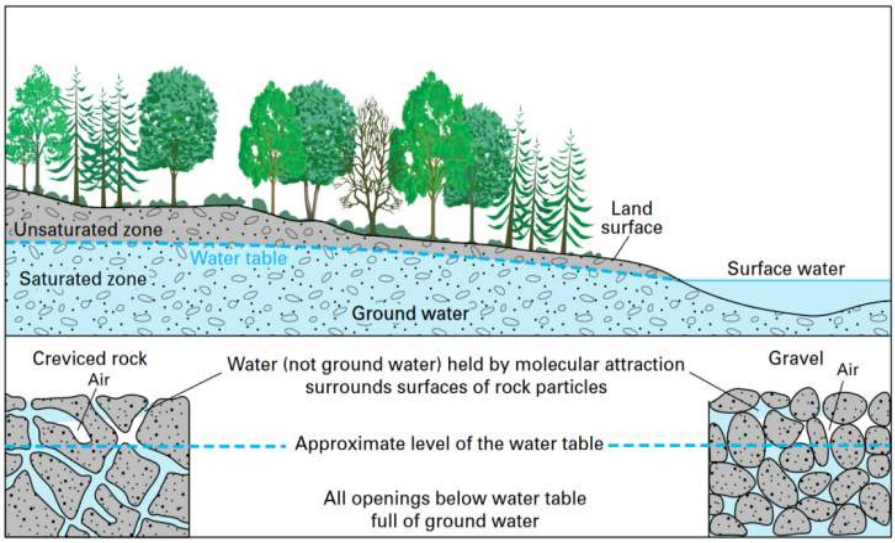

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

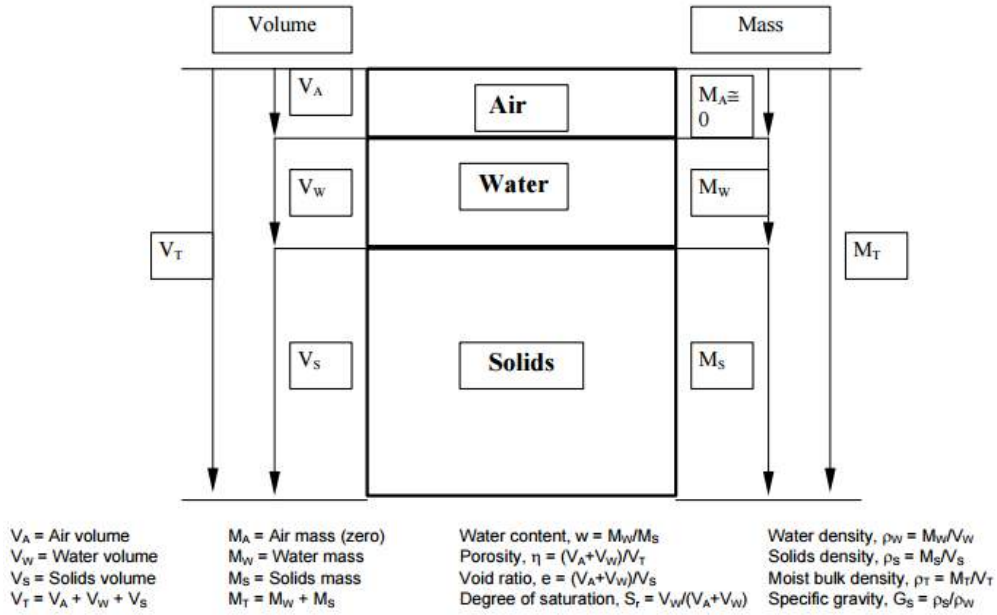

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

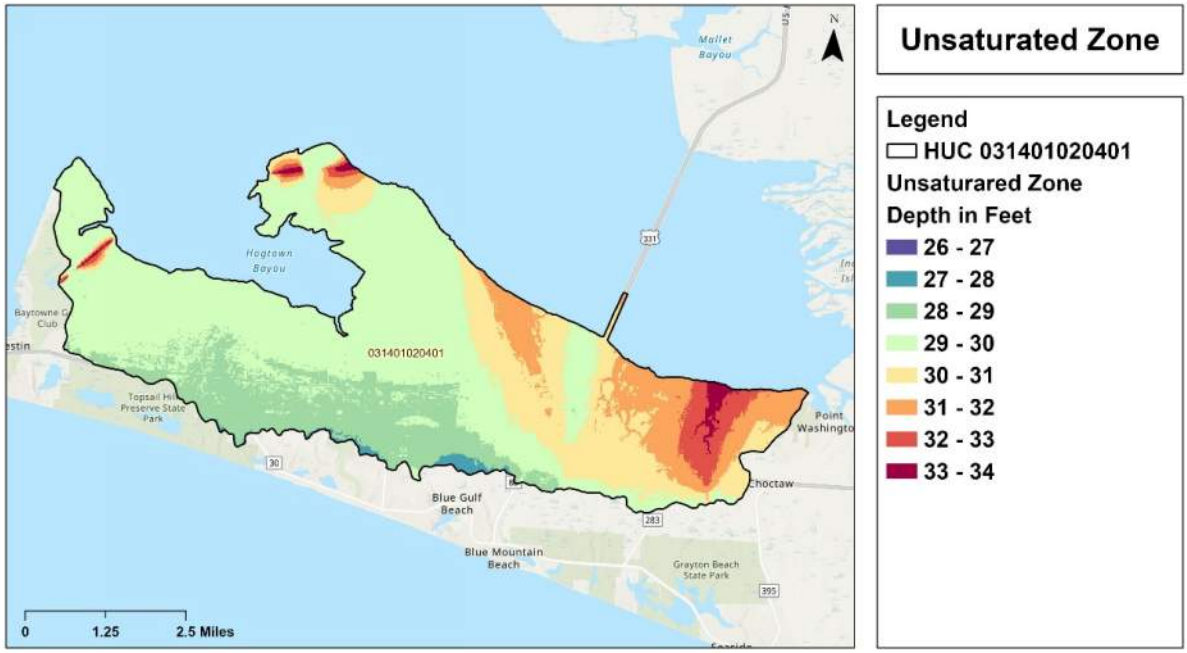

Figure 15. Unsaturated zone map for HUC 031401020401, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin demonstrates a moderately favorable soil storage capacity, falling within the range of 28 to 33 feet of remaining capacity.

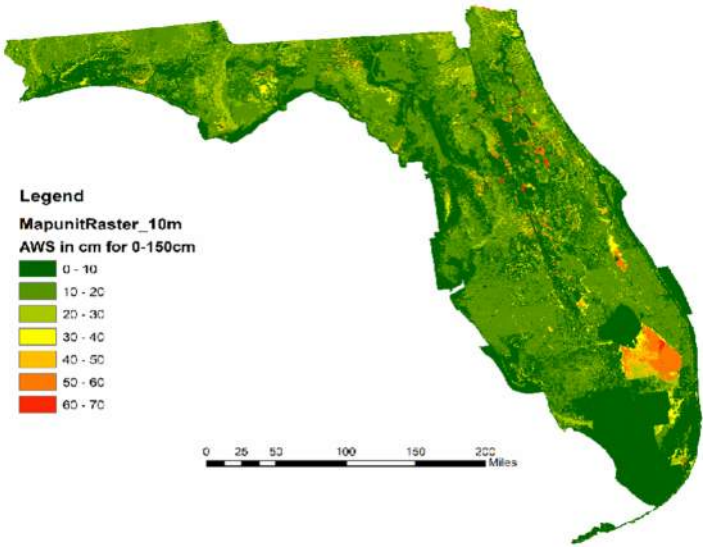

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

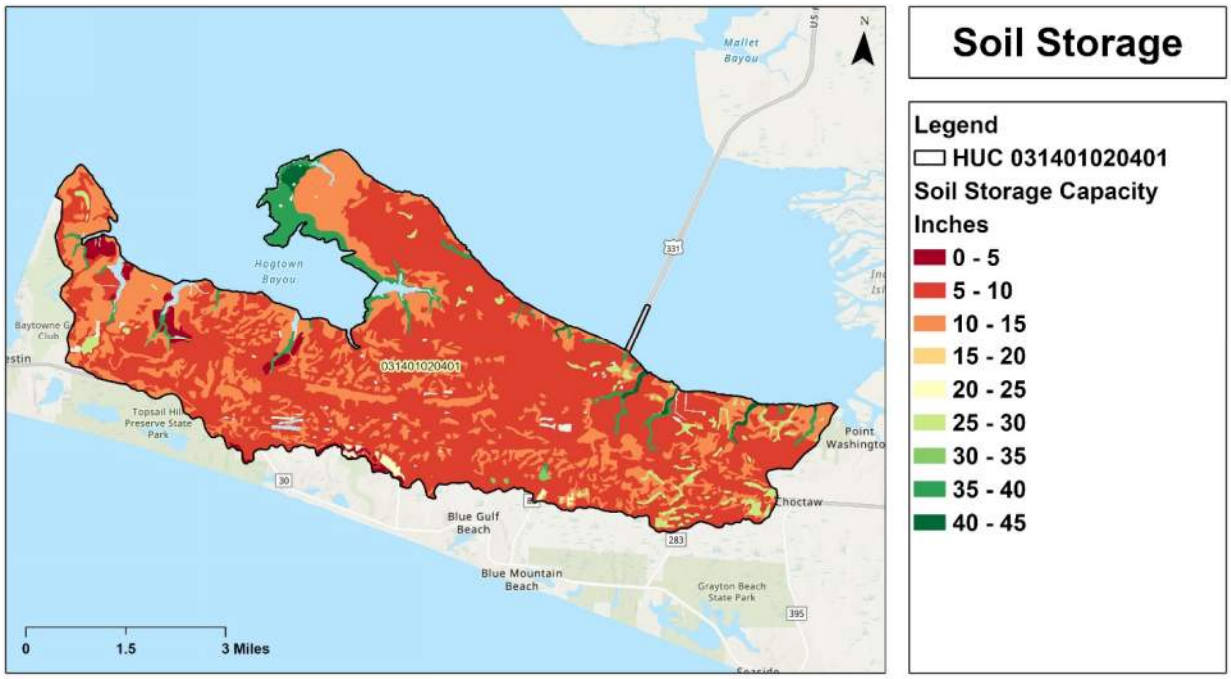

Figure 17. Water storage capacity of soil for the HUC 031401020401, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

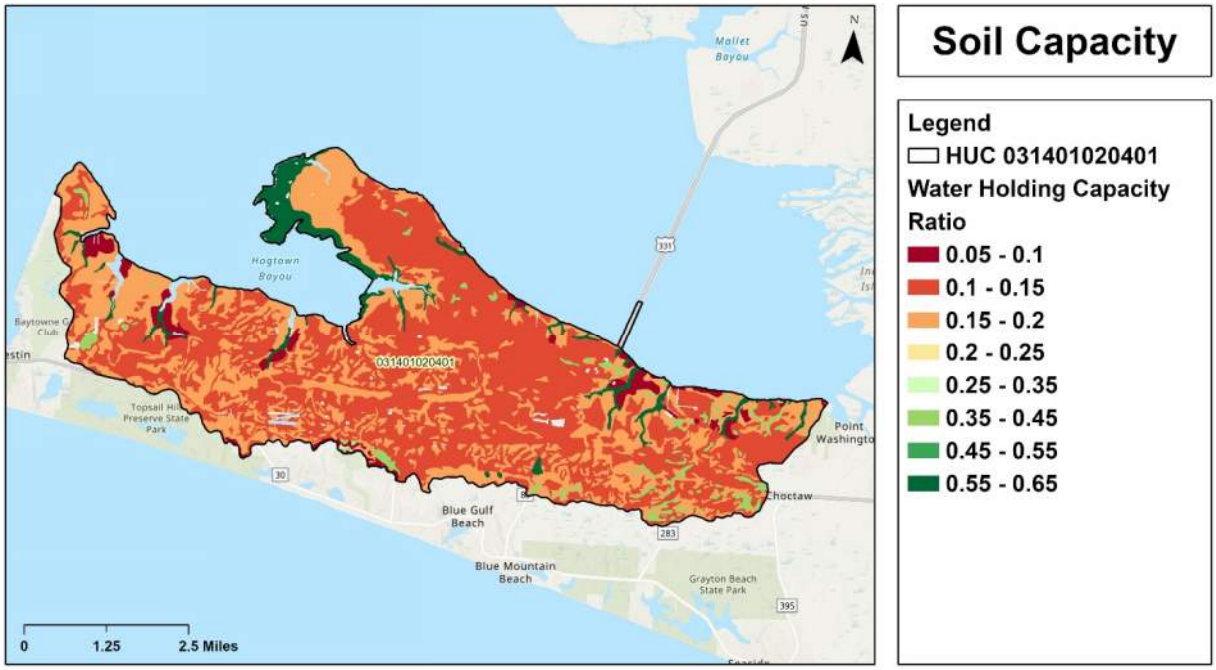

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020401, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

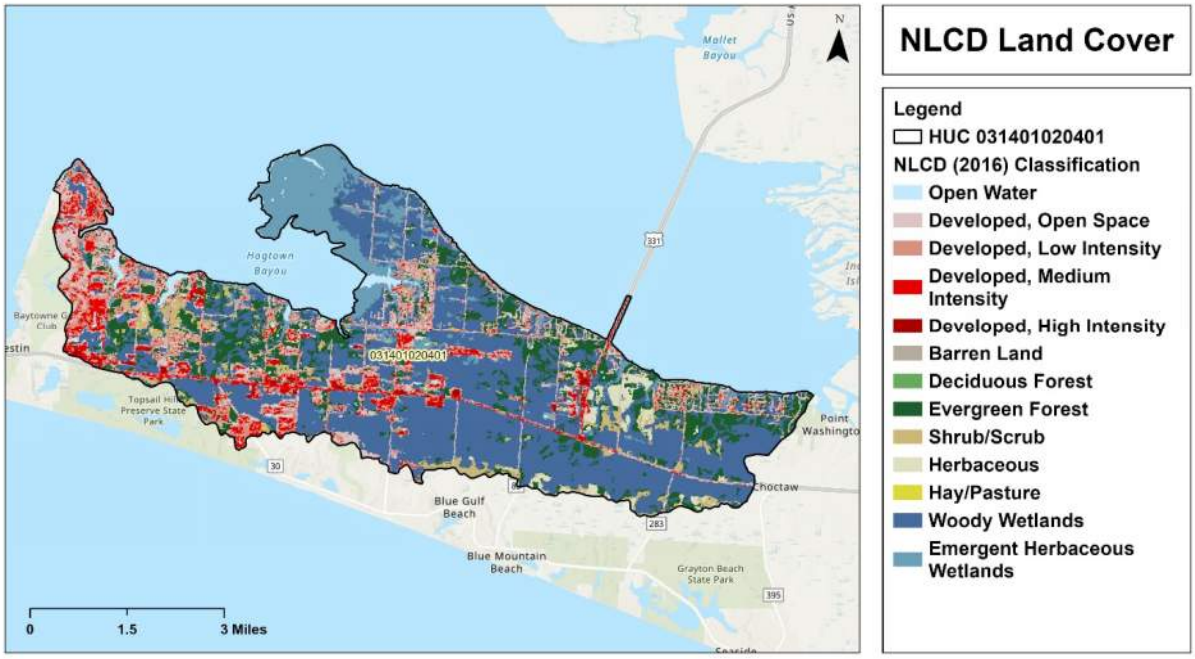

Figure 19. Land use in the HUC 031401020401 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

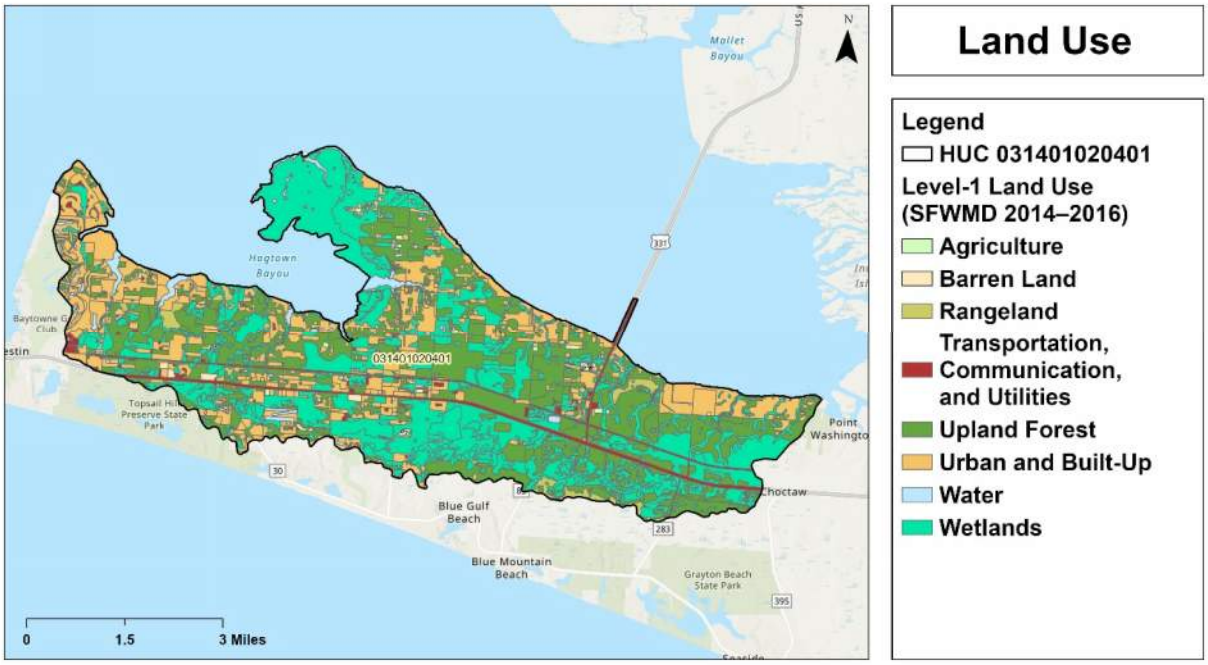

Figure 20. Land use in the HUC 031401020401 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031401020401 sub-watershed, the predominant is wetland, accounting for 31.58% of the area. Upland forest comes in second at 29.87%, followed by urban and built-up at 20.19%, as indicated in as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface. It is important to remember that the HUC 031401020401 covers the community of Santa Rosa Beach.

Table 3. Land use for HUC 031401020401 sub-watershed (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	57.54	0.24%
Barren Land	183.39	0.77%
Rangeland	611.26	2.56%
Transportation, Communication, and Utilities	1292.14	5.41%
Upland Forest	7136.70	29.87%
Urban and Built-Up	4823.58	20.19%
Water	2242.26	9.38%
Wetlands	7546.02	31.58%
Grand Total:	**23892.90**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

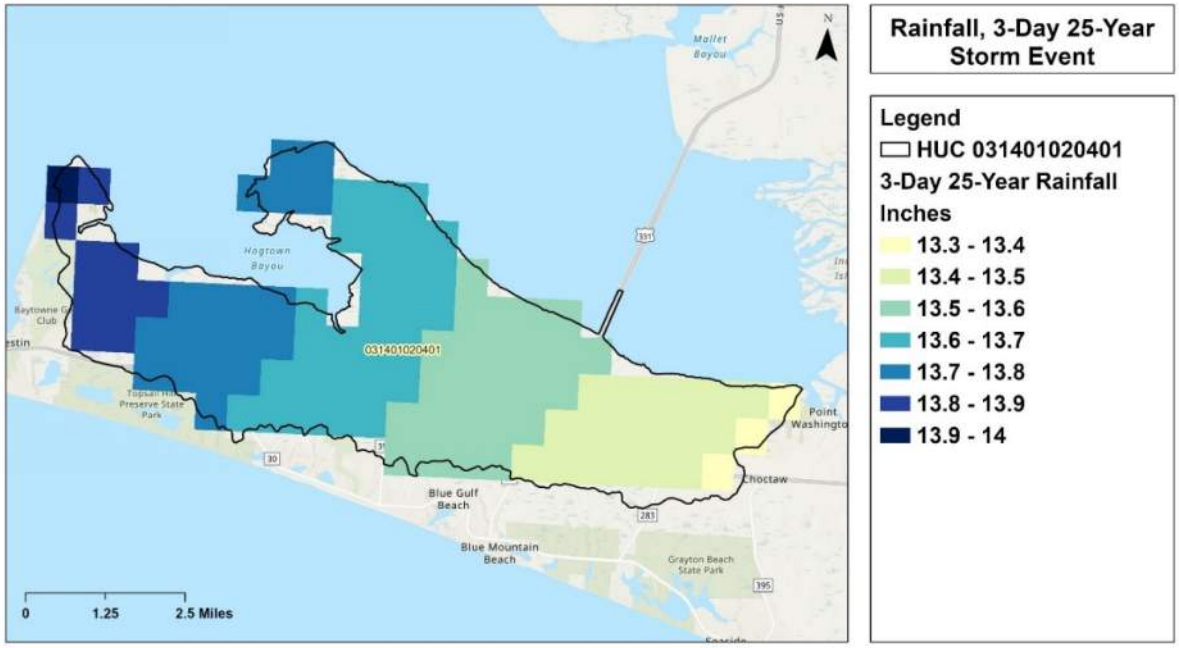

Figure 21. Rainfall distribution map across HUC 031401020401 sub-watershed, for 3-day 25-year storm event, processed by FAU.

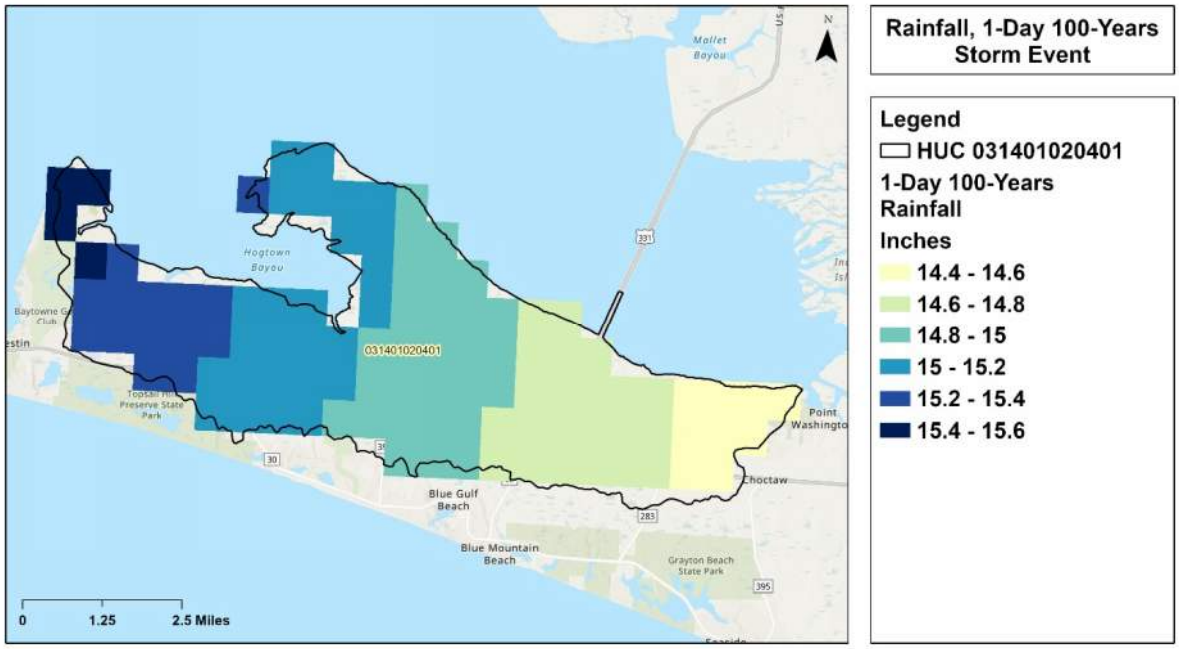

Figure 22. Rainfall distribution map across HUC 031401020401 sub-watershed, for 1-day 100-year storm event, processed by FAU.

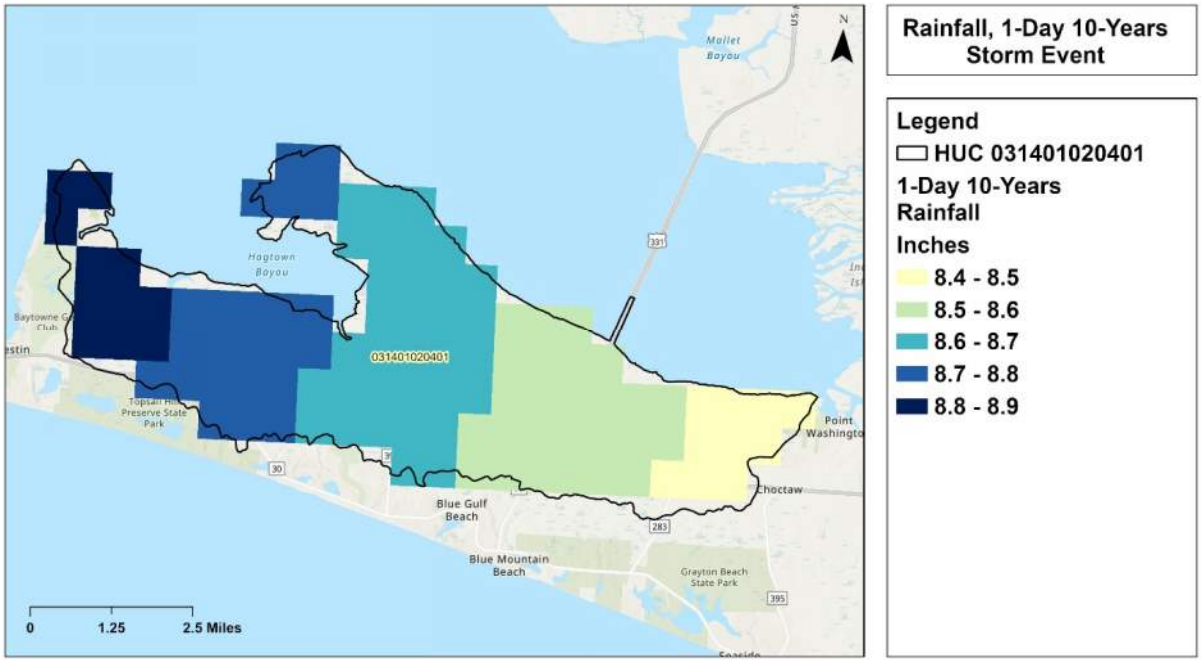

Figure 23. Rainfall distribution map across HUC 031401020401 sub-watershed, for 1-day 10-year storm event, processed by FAU.

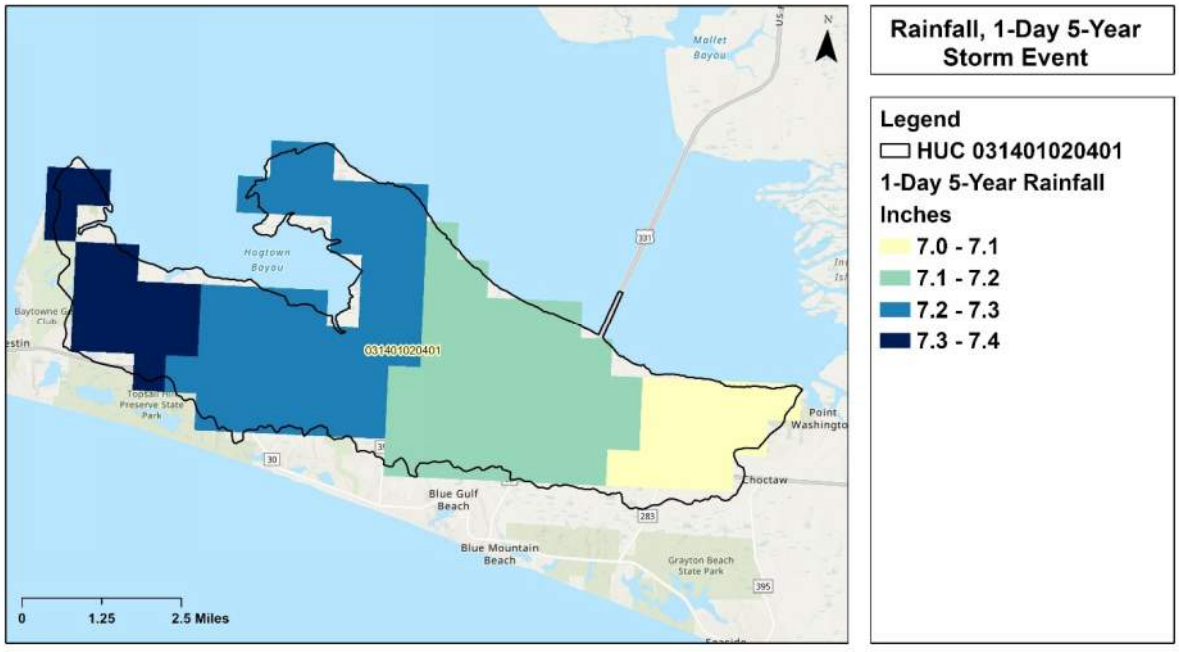

Figure 24. Rainfall distribution map across HUC 031401020401 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land

cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

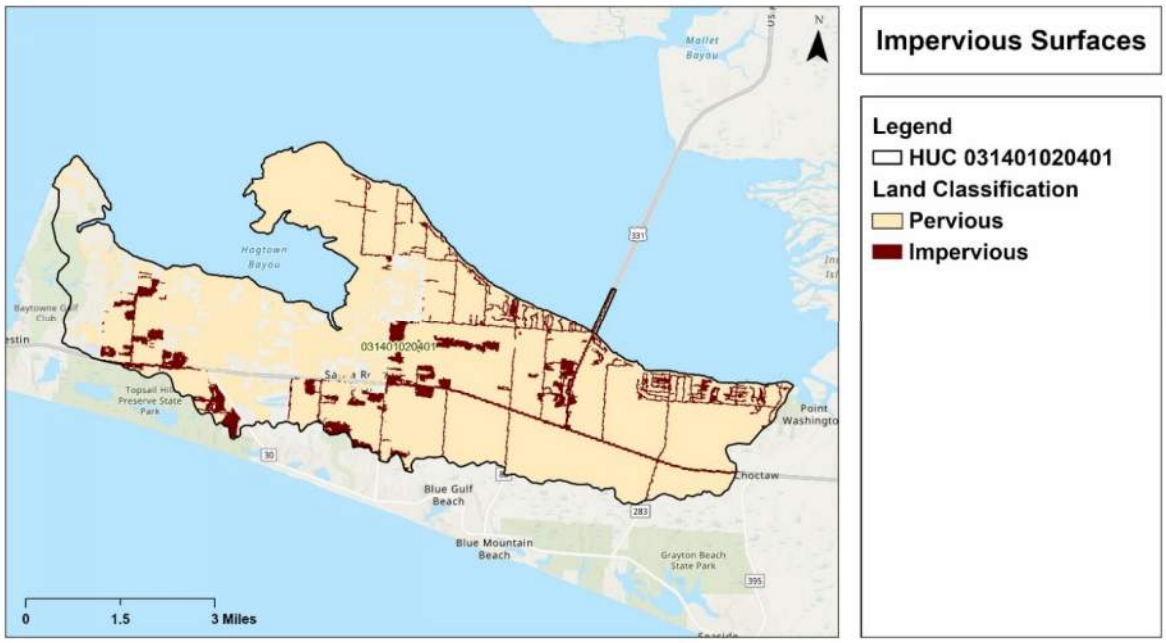

Figure 25. Impervious area map for the HUC 031401020401 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

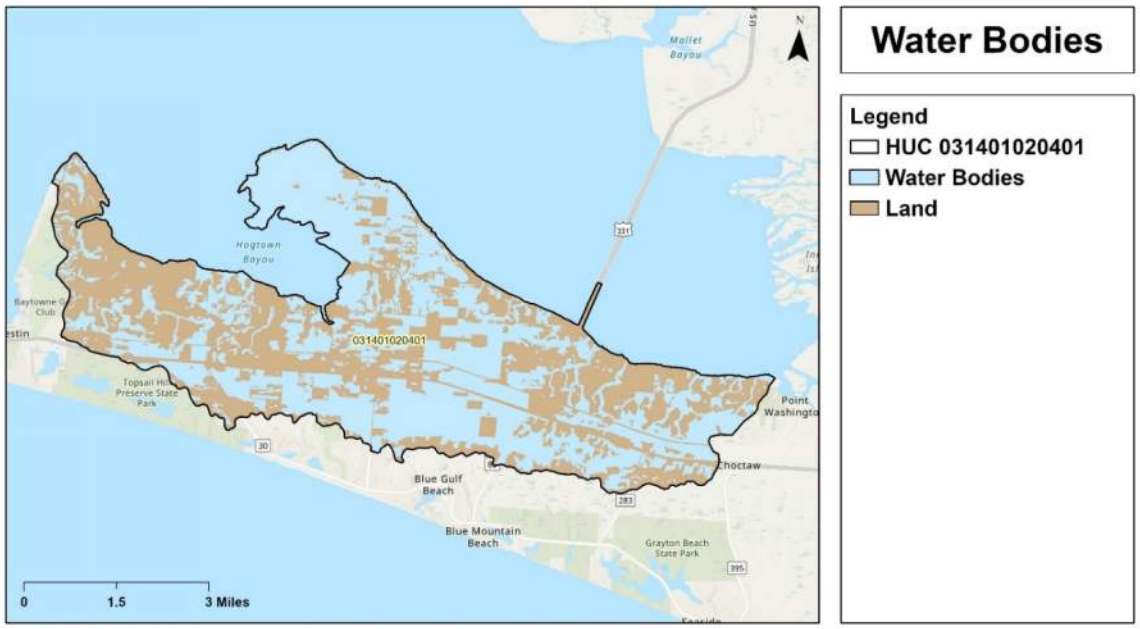

Figure 26. Water bodies map for the HUC 031401020401 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other

waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant

control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

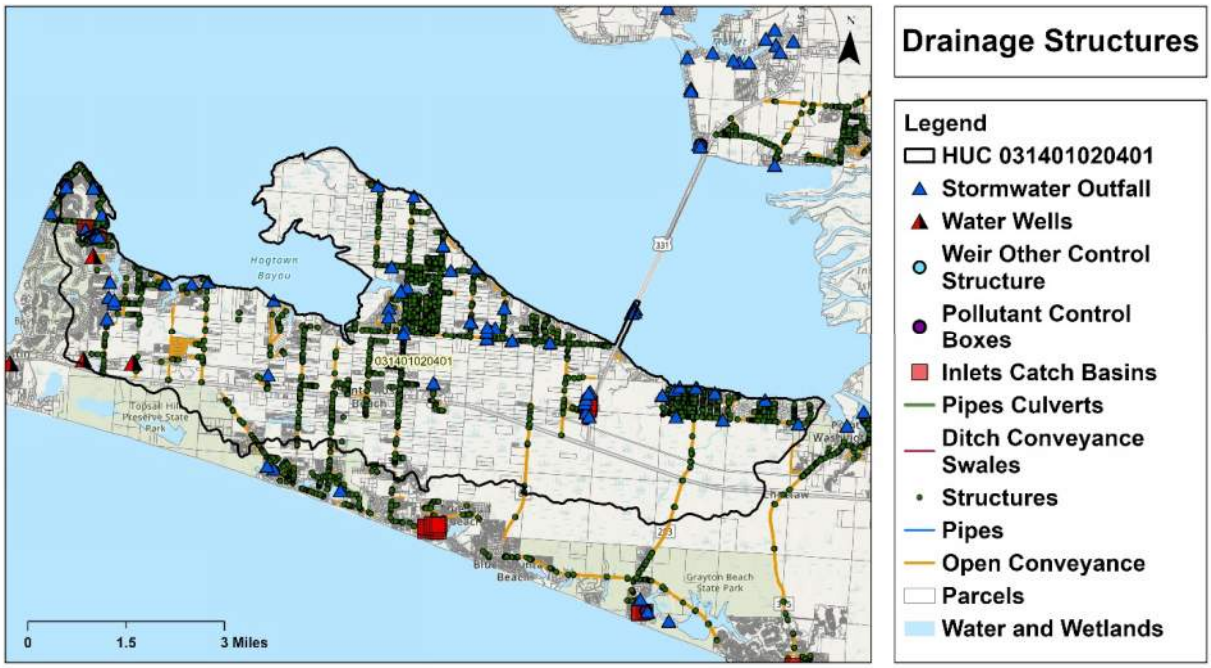

Figure 27. Stormwater Infrastructure for the HUC 031401020401. Processed by FAU.

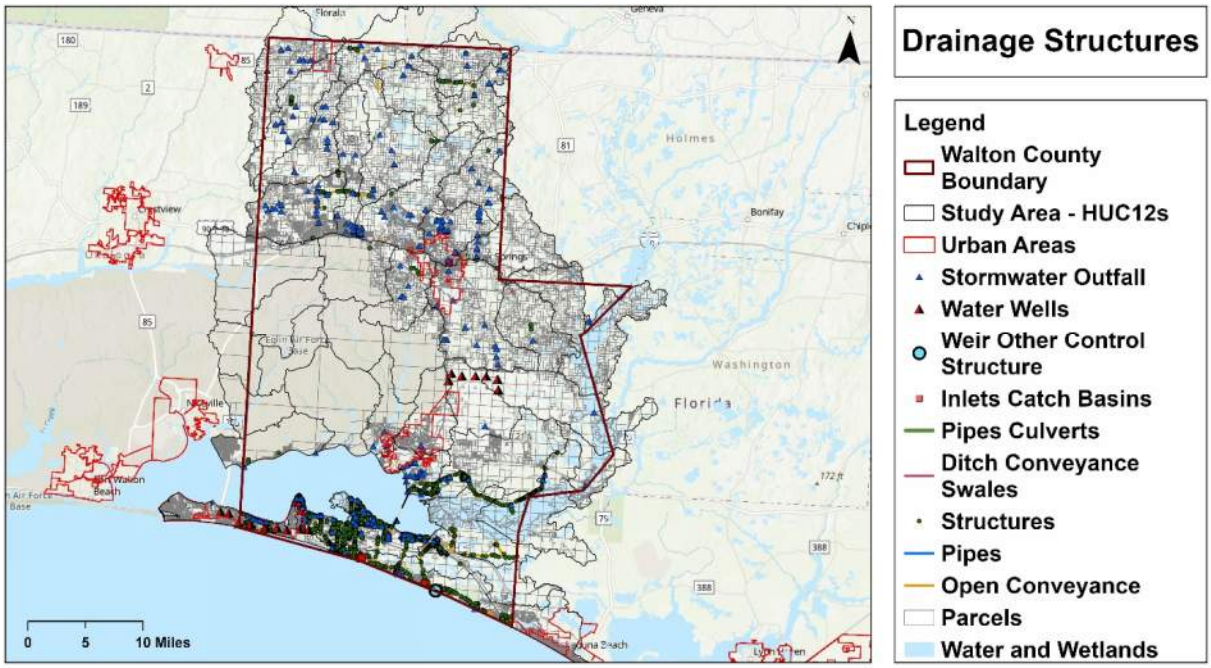

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in Table 5. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings, as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020401 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

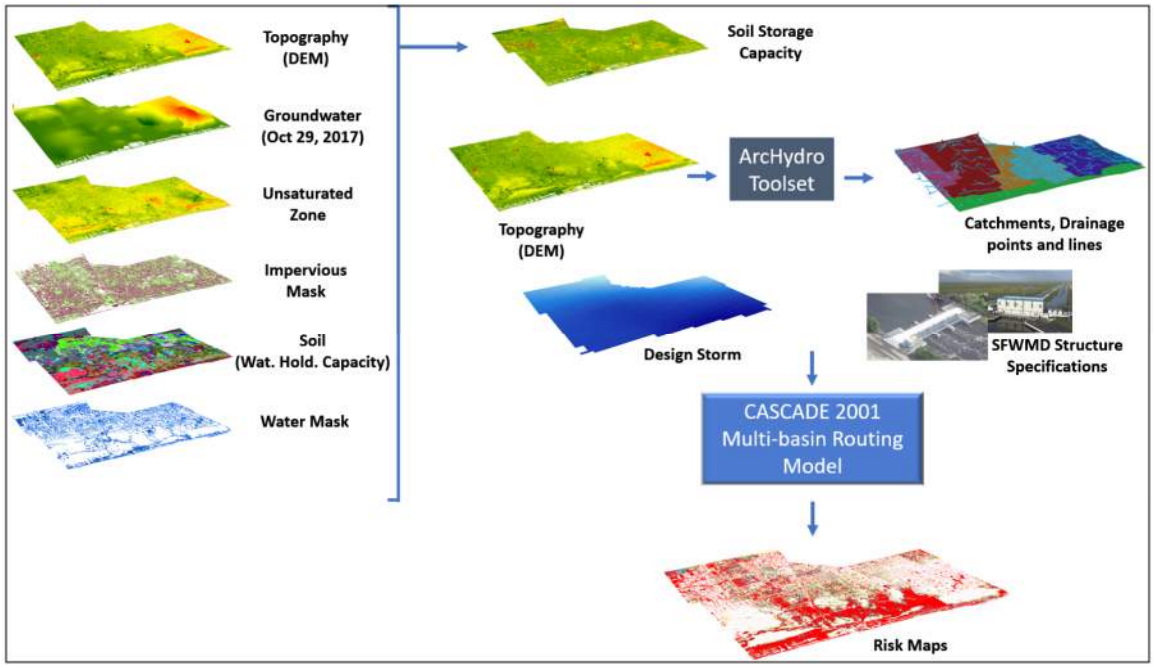

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

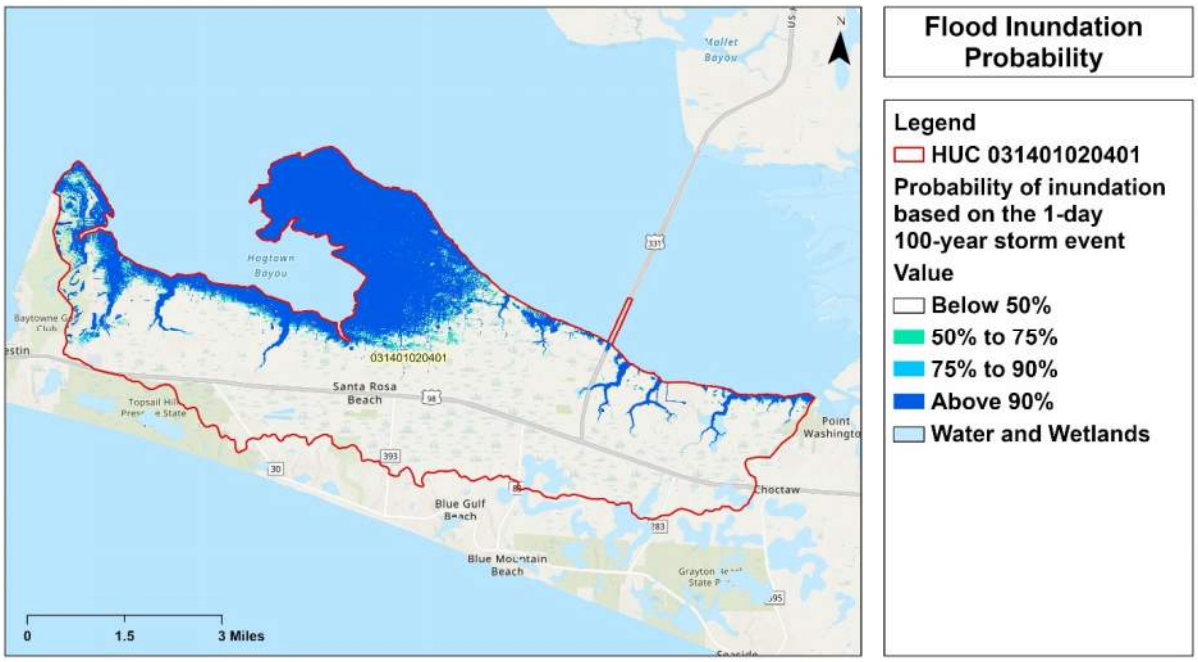

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020401, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data

to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Future Challenges of Sea Level Rise and Climate Change

Global observations from satellites and long-term data collection have made it possible to document and analyze patterns in the Earth's climate. Scientific analysis of the impact of these changes has helped to improve the understanding of future flood hazard driving forces and long-term impacts on human activities and watershed master planning (http://www.research.noaa.gov/climate/t_observing.html). Examples of impacts are rising global average air and ocean temperatures, increased and earlier snow and ice melt, shorter subtropical rainy seasons, shifted seasons, sea level rise and greater variations in temperature and precipitation (IPCC, 2013; Freas et al., 2008; Marshall et al., 2004; Bloetscher et al., 2010). Marshall et al. (2004) specifically focused on the Florida peninsula to predict changes in rainfall and warmer temperatures but interspersed lower low temperatures due to the potential loss of wetlands.

Future changes in climate will add to the existing impacts, at a time when the population of the state is expected to nearly double by 2030. Additional research and high-resolution climate modeling for the Florida peninsula and local jurisdictions is needed to help guide long-term plans like WMPs. Rainfall appears to be decreasing and temperatures rising (see **Error! Reference source not found.**).

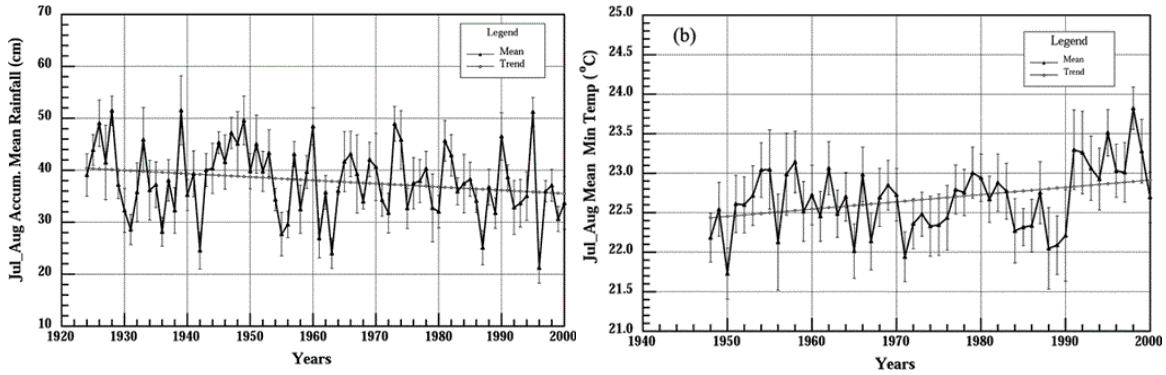

Figure 31. Change in average rainfall and change in average temp 1924 to 2000. Note the reversed trend, which means groundwater input variability is lessened. Source: Marshall et al., 2004.

Climate change is likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly compromised stormwater drainage systems, and d) more frequent inundation of barrier islands and coastal areas.

NOAA and IPCC (2013) predictions suggest that by 2100, global temperatures will be on the order of 2-3°C (3-5°F) higher and sea levels will rise by up to 3 feet. Accompanying these drivers are potential changes in storm frequency and intensity, desertification, population migration, ocean acidification and coastal flooding (IPCC, 2007), exacerbated by the land cover and land use changes, which are substantially impacted by the fluxes, timing and quality of precipitation (Adrians et al., 2003; Scanlon et al., 2005; Marshall et al., 2004; Salmun and Molod, 2006), and leading to changes in the timing of peak flows and volumes (Richey and Costa-Cabral, 2006).

The results of these climatic changes are likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to

the ocean, c) increasingly An outcome of these climatic patterns is that during the past 140 years, an increase in sea levels has been observed (Bloetscher, 2012), a worrying pattern since sea level rise is a permanent phenomenon, that can be catastrophic to low lying areas in the long-term. The question is how much and how soon? Various studies (Bindoff et al., 2007; Domingues et al., 2008; Edwards, 2007; Gregory, 2008; Vermeer and Rahmstorf, 2009; Jevrejeva, Moore and Grinsted, 2010; Bloetscher, 2010, 2011; IPCC, 2007; Heimlich et al., 2009) indicate large uncertainty in projections of sea level rise by 2100. Gregory et al. (2012) note that during the last two decades, the global rate of sea level rise has been larger than the 20th-century time-mean, and Church et al. (2011) suggested that the cause was increased rates of thermal expansion, glacier mass loss, and ice discharge from icesheets. Gregory et al. (2012) suggested that there may also be increasing contributions to global sea level rise from the effects of groundwater depletion, reservoir impoundment, and loss of storage capacity in surface waters due to siltation. Measurements of Florida's east coast (Maul, 2008) show an average rate of sea level rise of 2.27 ± 0.04 mm per year from 1915 to 1992 based on tide gauge readings. Analyzing the tidal gauge readings for Florida shows that:

1. Florida average sea level rise is 2.10 ± 0.49 mm/yr
2. All but one location is within the 95% confidence limit range (the exception is Panama City where there is evidence of submergence and other land-based issues)
3. None of the Florida sea level rise rates differ statistically
4. Average global sea level rise for 1920-2000 was 2.0 mm/yr – within 95% confidence limit for Florida locations

From 1929 to 1992, over eight inches of sea, with another 6 inches added since 1992, which is already having significant impacts on coastal communities where population growth has increased the need for improved flood management strategies (Bloetscher, 2008; Parkinson, 2010; Zhang et al., 2011, 2011a; NFIP, 2011; Schmidt et al., 2011; Warner et al., 2012).

As a result, the SFRCCC (2015) adopted USACE's methodology to derive scenarios of sea level change intermediate to high rates of sea level rise for years 2030 (3" to 7") and 2060 (9" to 24") as the consensus projection to guide future planning. The path keeps increasing – now 14 inches since 1929 (**Error! Reference source not found.**) caused by thermal expansion of the ocean and melting ice caps (Jevrejeva et al., 2010; Vermeer and Rahmstorf, 2009). Sea level rise is a major concern in Florida, including Walton County, since the majority of the state's population live on the coast, involving most major commercial, residential, and economic enterprises. **Error! Reference source not found.** demonstrate the estimated sea level change for Panama City, considering the predictions of NOAA 2017. For NOAA high scenario SLR change scenario, the estimated level change is higher than 8 ft., while for the intermediate and low scenarios are about 3.9 feet and 1.7 feet respectively.

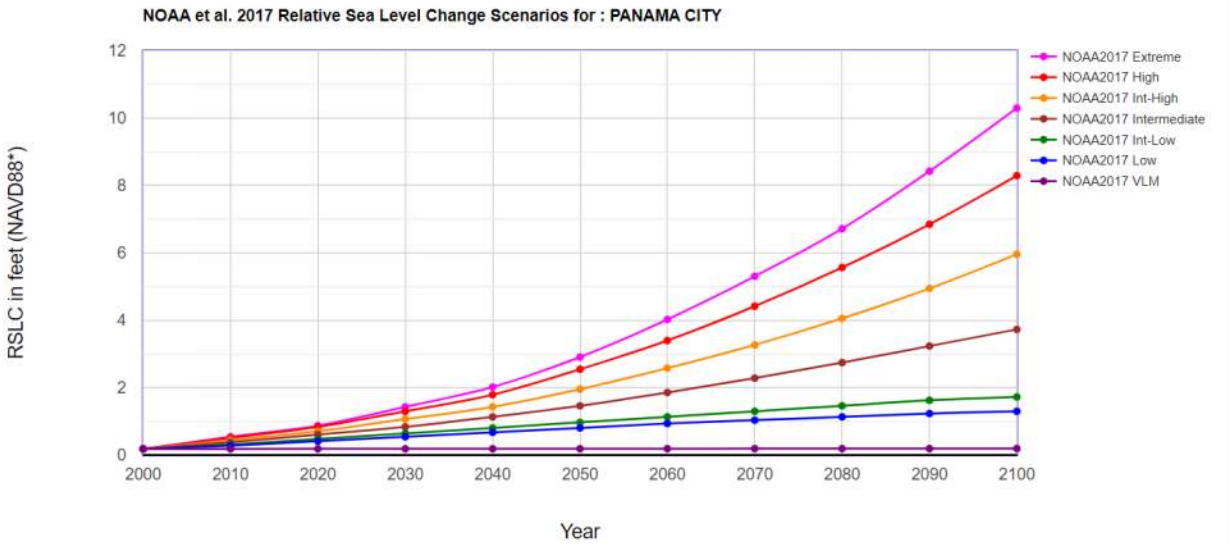

Figure 32. Relative Sea Level Change Scenarios for gauge 8729108, Panama City, FL. Source: NOAA, 2017 (https://cwbi-app.sec.usace.army.mil/rccslc/slcc_calc.html).

NOAA (2017) outlines five scenarios for sea level rise. The NFIP proposes the use of the intermediate high projection, which is 1.2 meters or 4 ft globally from current sea level elevations (**Error! Reference source not found.**).

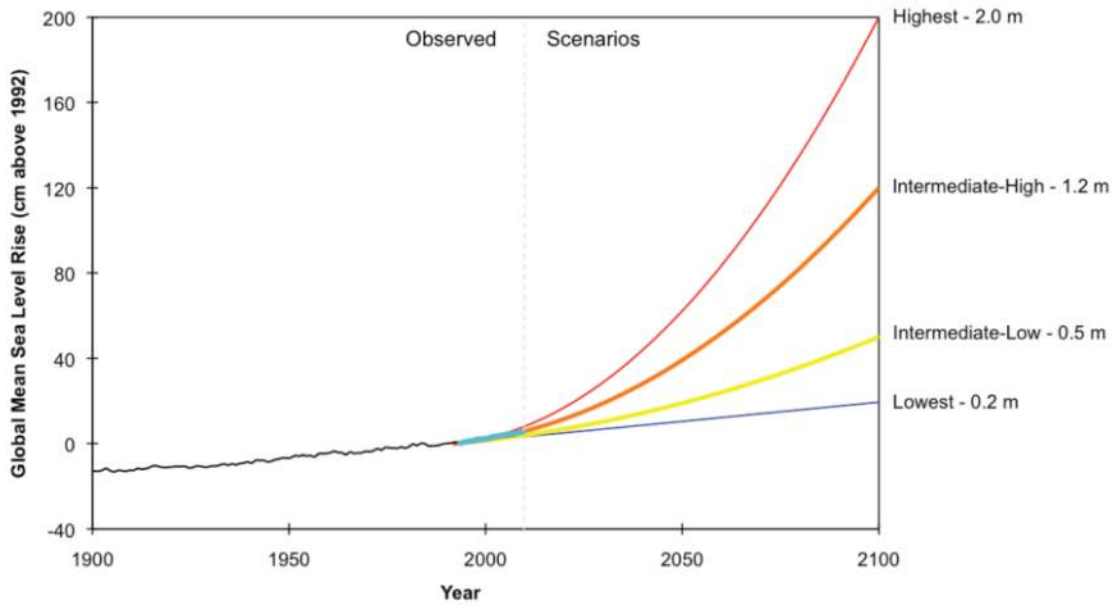

Figure 33. Graphic of global sea level rise projections from NOAA (2017). Source:https://tidesandcurrents.noaa.gov/publications/techrpt83_Global_and_Regional_SLR_Scenarios_for_the_US_final.pdf

As sea level rises, access to roads, bridges, rail, and transit could be at risk of flooding, causing the effects of sea level rise to spread indirectly throughout the entire transportation network, affecting the overall system performance. For example, the flooding of a critical road or facility access can cause a shifting of traffic flow causing congested conditions in other roadways that are not actually flooded. Since the roadway network would be unable to carry the traffic demand, the system would experience operational failure; as a result, causing travel times and delays. Moreover, the inundation of a critical access could cause transportation connectivity problems to essential infrastructure like ports or airports. Transportation infrastructure relies on the effectiveness of flood control and stormwater drainage systems for the transportation corridors. Road integrity relies on adequate drainage. The increased risk of severe flooding in Florida's low-lying terrain can adversely affect transportation infrastructure along the coastline; roads can be inundated, and roadway beds can be damaged. Sea level rise will cause increased water table levels (FDOT, 2012), as regional water tables cannot exist naturally below mean high tide (2 feet in Florida). Adding 3 feet of sea level rise on top of groundwater would compound the risk of flooding in low-lying areas. Road bases below 5 feet NVGD would become saturated under this scenario, likely causing premature base failure. As soil storage capacity is diminished due to rising groundwater elevations associated with sea level rise, the potential for more frequently flooded roadways would likely damage pavements (FDOT, 2012). Hence sea level rise must be accounted for in WMPs in coastal areas. To allow flexibility in the analysis due to the range of increases within the different time periods, an approach that uses incremental increases of 1, 2, and 3 feet of sea level rise is suggested for modeling. The increments can work as threshold values in planning considerations in terms of allowing planners the ability to know ahead of time where the next set of vulnerable areas will be, to allow for a proactive response approach that can be matched to the observed future rates. Sea level rise is a major concern since nearly half the US population lives within 50 miles of the coast, involving most major commercial, residential, and economic enterprises. The effects of 5 ft sea level rise, King tide, and 1-day 100-year storm event are shown in **Error! Reference source not found.**.

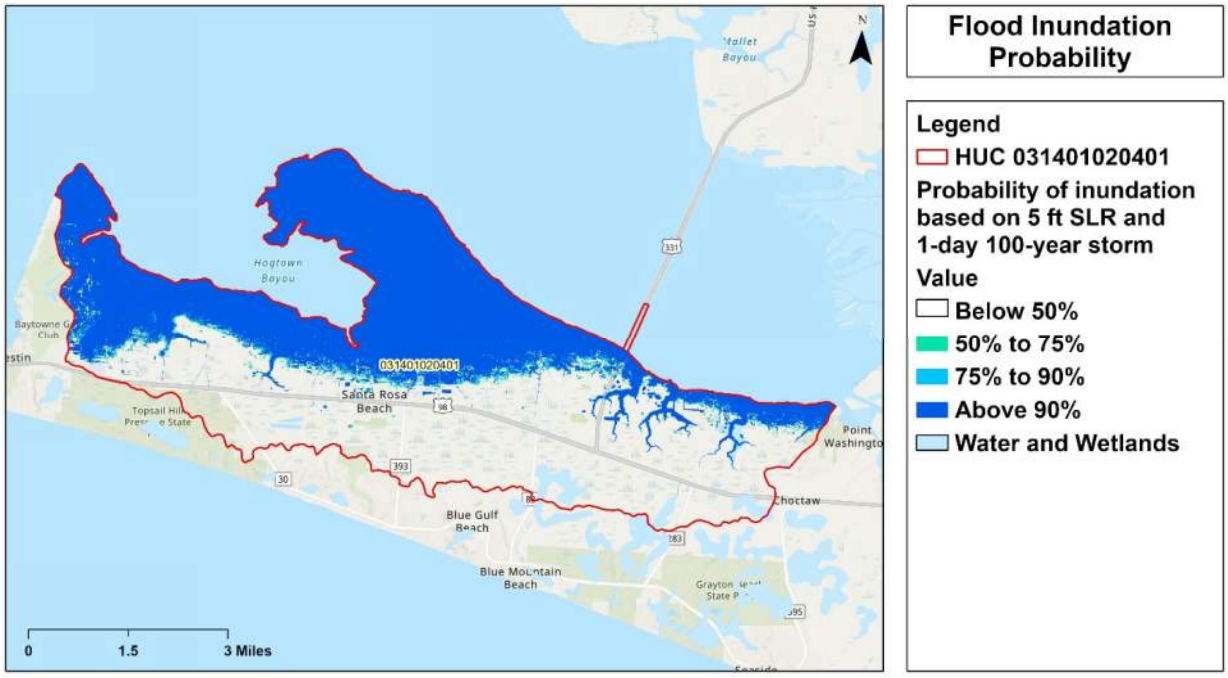

Figure 34. Flood Inundation Probability for a Sea level rise of 5 ft + 1-day 100-year storm event for HUC 031401020401 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations.

2.4 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. **3-day 25-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 35)
2. **1-day 100-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 36)
3. **1-day 10-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 37)
4. **1-day 5-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 38)
5. **Sea level rise of 1 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 39)

6. **Sea level rise of 1 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations storm (Figure 40)
7. **Sea level rise of 1 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 41)
8. **Sea level rise of 1 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 42)
9. **Sea level rise of 2 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 43)
10. **Sea level rise of 2 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 44)
11. **Sea level rise of 2 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 45)
12. **Sea level rise of 2 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 46)
13. **Sea level rise of 3 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 47)
14. **Sea level rise of 3 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 48)
15. **Sea level rise of 3 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 49)
16. **Sea level rise of 3 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 50)
17. **Sea level rise of 4 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 51)
18. **Sea level rise of 4 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 52)

19. **Sea level rise of 4 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 53)
20. **Sea level rise of 4 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 54)
21. **Sea level rise of 5 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 55)
22. **Sea level rise of 5 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 56)
23. **Sea level rise of 5 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 57)
24. **Sea level rise of 5 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 58)

In all scenarios, a considerable amount of flooding is noted along the coast and, following the waterbodies flow path. As this basin connects to the ocean though Choctawhatchee River, SLR scenarios plays an important hole, implying a considered growth as the projected scenario of rising tides rises.

The design storm simulation determined that approximately 26% of the HUC total area or 7.78 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 27.3% of the HUC's total area, or 8.18 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 24.3% of the HUC's total area, or 7.29 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 23.6% of the HUC's total area, or 7.08 mi², would be expected to be inundated during the 1-day 5-year storm. Table 7 compares the four storm events.

Table 7. HUC 031401020401 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	22.09	7.78	73.8%	26.0%
1-day 100-year	21.69	8.18	72.5%	27.3%
1-day 10-year	22.59	7.29	75.5%	24.3%
1-day 5-year	22.80	7.08	76.2%	23.6%

2.5 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.5.1 Results

Error! Reference source not found. to **Error! Reference source not found.** depict the HUC 031401020401 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 60) overlays critical facilities onto the 1-day 100-year storm event scenario, while the third map (**Error! Reference source not found.**) represents the same overlay within the context of 5 feet of sea level rise (SLR) combined with the 1-day 100-year storm event. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 5 feet SLR + 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** and **Error! Reference source not found.** illustrate the composite score for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. **Error! Reference source not found.** represents the calculation for composite score based on 1-day 100-year storm event, while **Error! Reference source not found.** shows the calculation for composite score for the same storm event, but including a 5 feet of Sea Level Rise scenario. **Error! Reference source not found.** shows the same area zoomed out.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.5.2 Drill-down – Santa Rosa Beach

For enhanced visualization of the urban areas within this HUC 031401020401, **Error! Reference source not found.** to **Error! Reference source not found.** illustrate the same results for critical facilities (land use priorities) and composite scores, but on a reduced scale, which better facilitates the examination of finer details within the urban area (Santa Rosa Beach). These maps cover both the 1-day 100-year scenario and the 1-day 100-year + 5 feet SLR scenario.

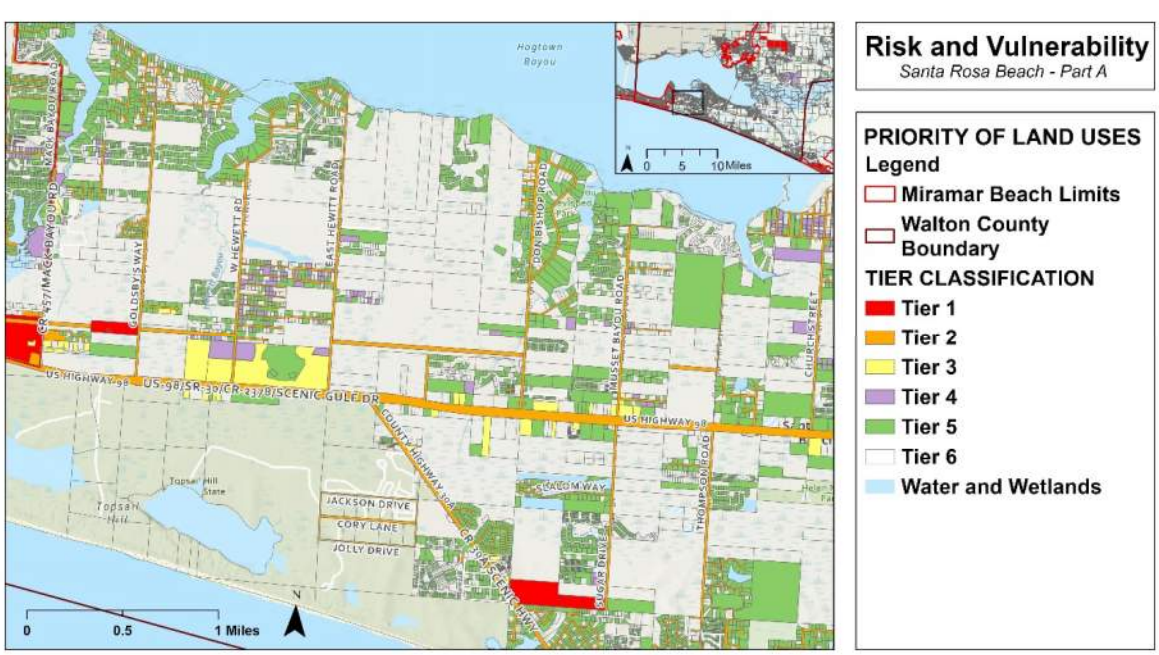

Figure 66. Critical Facilities (priority of land uses) map for Santa Rosa Beach (part A). Processed by FAU.

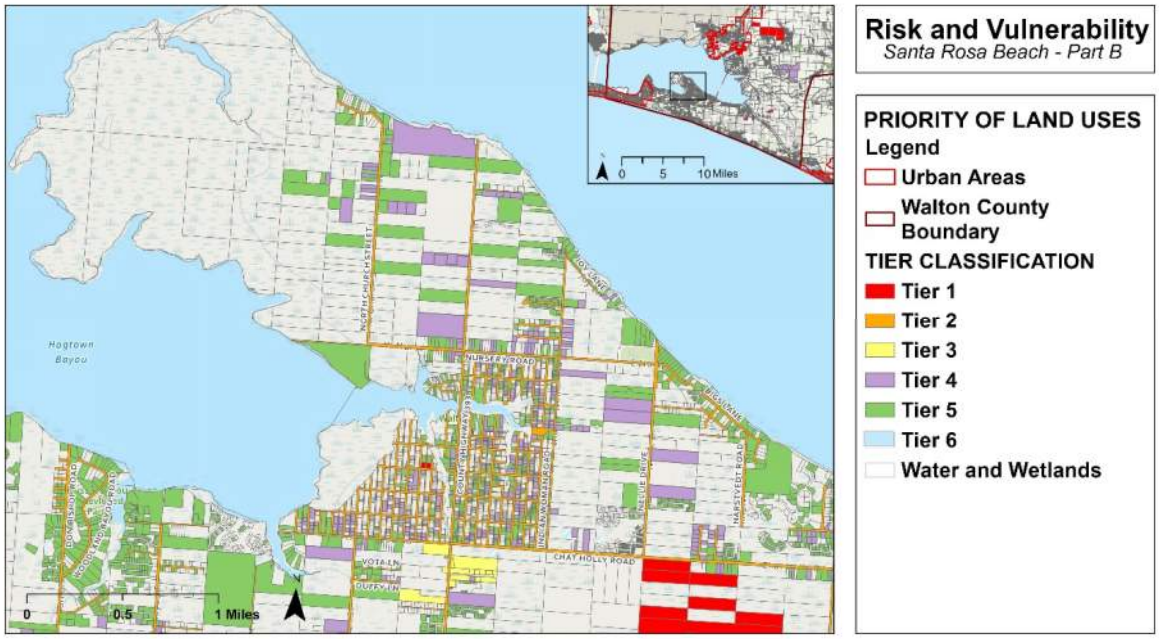

Figure 67. Critical Facilities (priority of land uses) map for Santa Rosa Beach (part B). Processed by FAU.

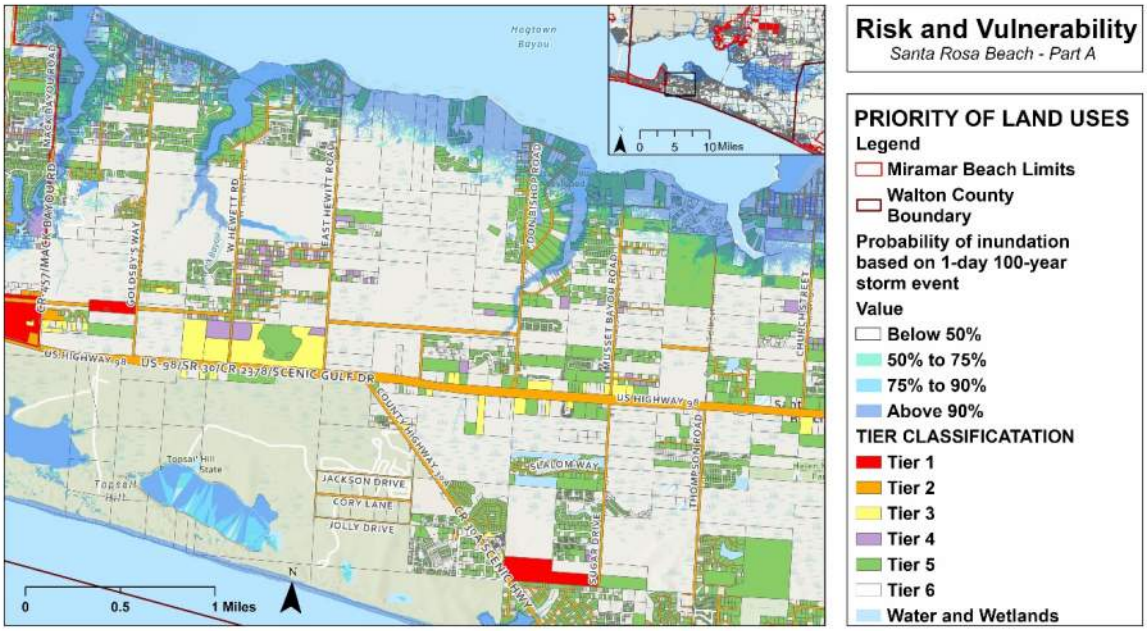

Figure 68. Critical Facilities (priority of land uses) map overlaid in the 1-day 100-year storm event for Santa Rosa Beach (part A). Processed by FAU.

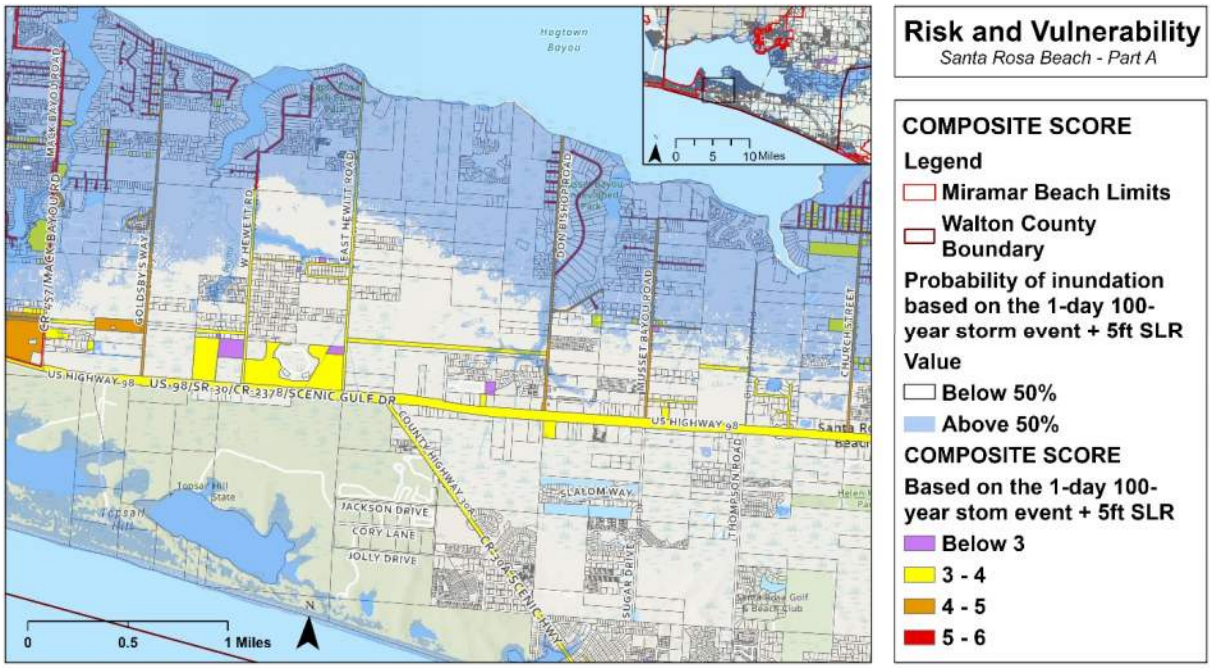

Figure 74. Composite Score map based on 1-day 100-year storm event + 5 feet SLR, overlaid in flooding layer for Santa Rosa Beach (part A). Processed by FAU.

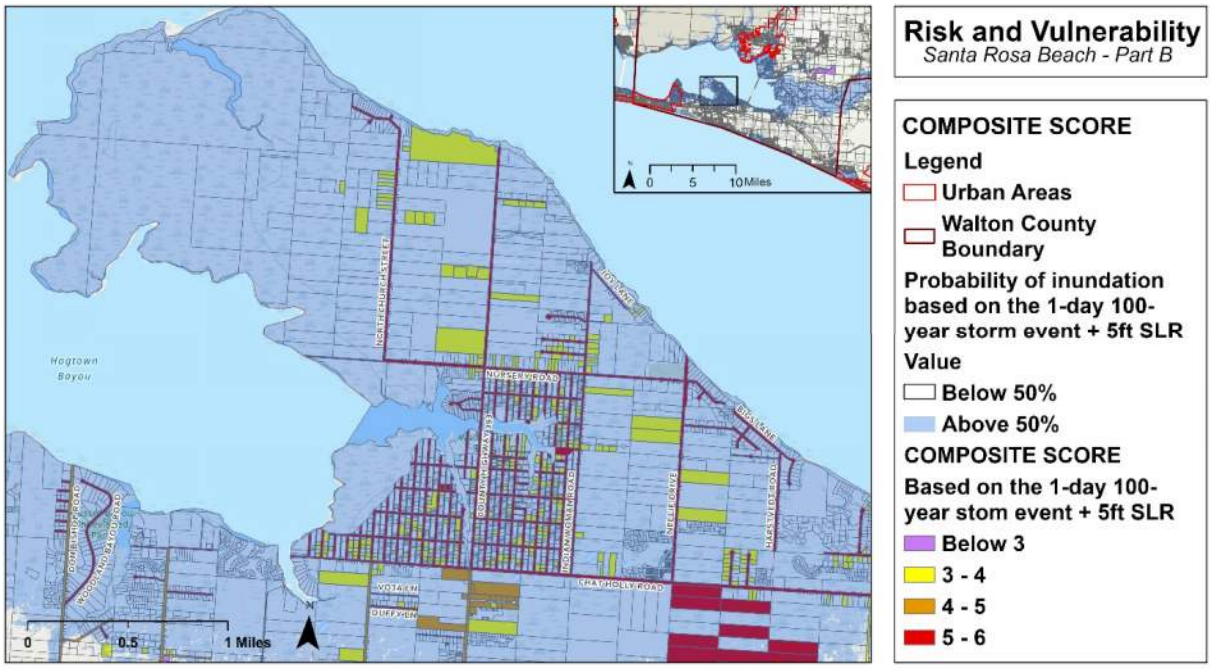

Figure 75. Composite Score map based on 1-day 100-year storm event + 5 feet SLR, overlaid in flooding layer for Santa Rosa Beach (part B). Processed by FAU.

2.5.3 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020401. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**.. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.5.4 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020401. Processed by FAU.

AREAS	ACRES
HUC-12 Sub-watershed: 031401020401	19156.62
All of the 1-day 100-year storm event inundation	**5235.98**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	1195.95
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	169.22
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	2.80
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	4040.03
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	3868.01

2.5.5 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

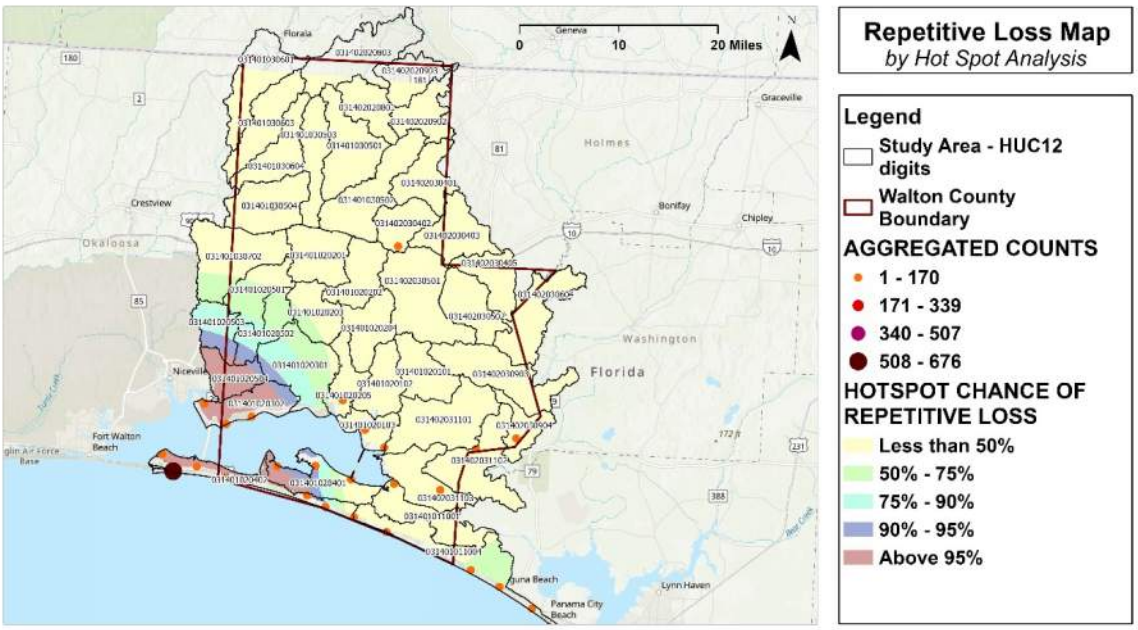

Figure 76. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.5.6 Priority Projects

The basin encompasses the community of Santa Rosa Beach, featuring a significant amount of developed land. Unfortunately, a substantial portion of this community is at risk of flooding, especially during a 1-day 100-year storm event + 5 ft. SRL scenario.

In terms of land use priority, there are 30 critical facilities (tier 1) within the basin, although not all are within the flood zone. Additionally, there are 473 parcels categorized as tier 2, including four financial institutions, four private schools, and numerous roads, with a significant portion within the flood zone. The basin also includes 98 parcels categorized as tier 3, 590 as tier 4, and over 6,900 as tier 5. Many of these parcels are within the flood zone.

Examining the composite score provides more detailed information about parcels within the flood zone. A total of 967 parcels are affected by the 1-day 100-year storm event + 5 ft. SRL scenario, and 746 parcels by the 1-day 100-year storm event alone.

In the worst scenario (1-day 100-year storm event + 5 ft. SRL), 381 parcels fall within the score range of 5-6, representing the highest priority for intervention. These include 8 county public schools, 5 utilities, and all remaining are roads, such as W Shipwreck Rd, Chat Holly Road, County Highway 393, North Church Street, Shelter Cove Dr/Pelican Bay Dr, Chat Holly Road, Rendevous Drive, 5th Street, etc.

Within the score range of 4-5, there are 56 parcels, including 3 community shopping centers, 14 office buildings, 2 professional service buildings, 2 restaurants/cafeterias, 9 light manufacturing facilities, 2 public schools, 1 college, 1 hospital, 7 utilities, and 11 roads, such as Cypress Point

Ln, W Point Washington Rd, Church Street , Goldsby's Way, County Road 393, Co Highway 283 N, and Mason Ave.

Within score 3-4, there are 495 parcels, including 426 mobile homes, 1 retirement home, 3 regional shopping centers, 3 community shopping centers, 5 office buildings, 3 restaurants, 1 financial institution, 1 auto sales/repair, 4 private schools and colleges, 11 orphanages or other non-profit service facilities, and 32 roads.

Additionally, the neighborhood of Long Leaf Circle in Santa Rosa Beach has shown a high interest in addressing flooding issues, as it has experienced multiple flooding incidents, affecting properties. This area includes parcels within score 3-4 and below 3 in the composite score calculations, indicating it should also receive priority for flood risk mitigation projects.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 sub-watershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub- watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020402) is highlighted among all the HUCs to help identifying its location. (Figure 3).

The cities of Destin, which is outside Walton County's boundary, Miramar Beach, and the community of Sacred Oaks are situated within the HUC 0314010402 boundary. Demographic data and other relevant information about these locations, as well as other cities and communities in Walton County, will be covered in subsequent discussions.

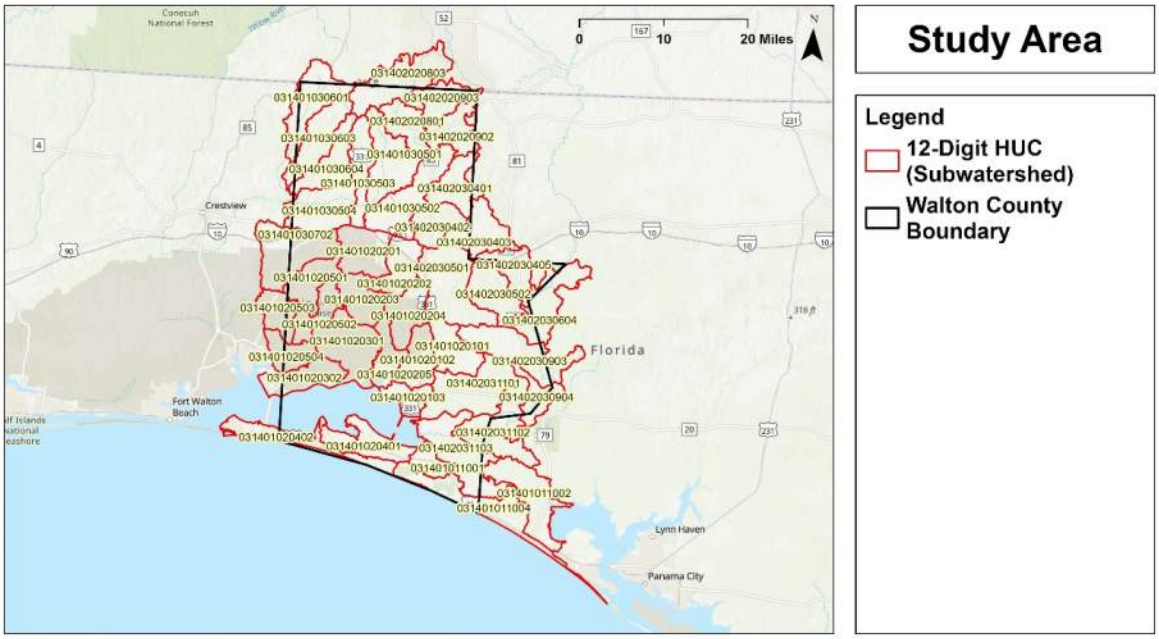

Figure 1. Walton County and all HUCs 12-digit sub-watershed, processed by FAU.

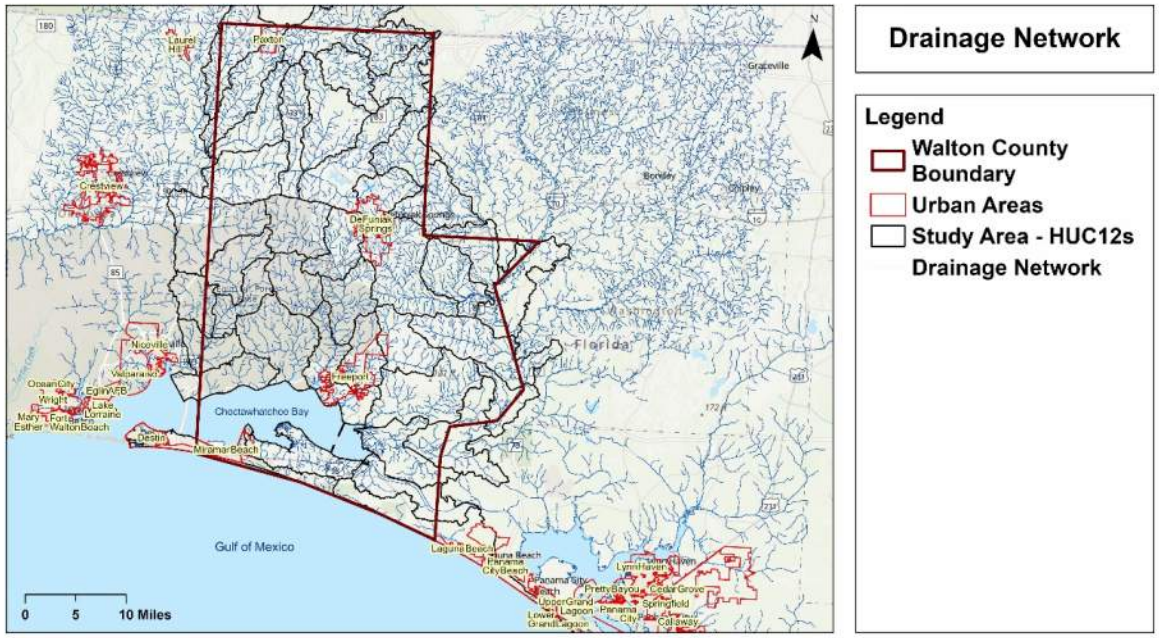

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

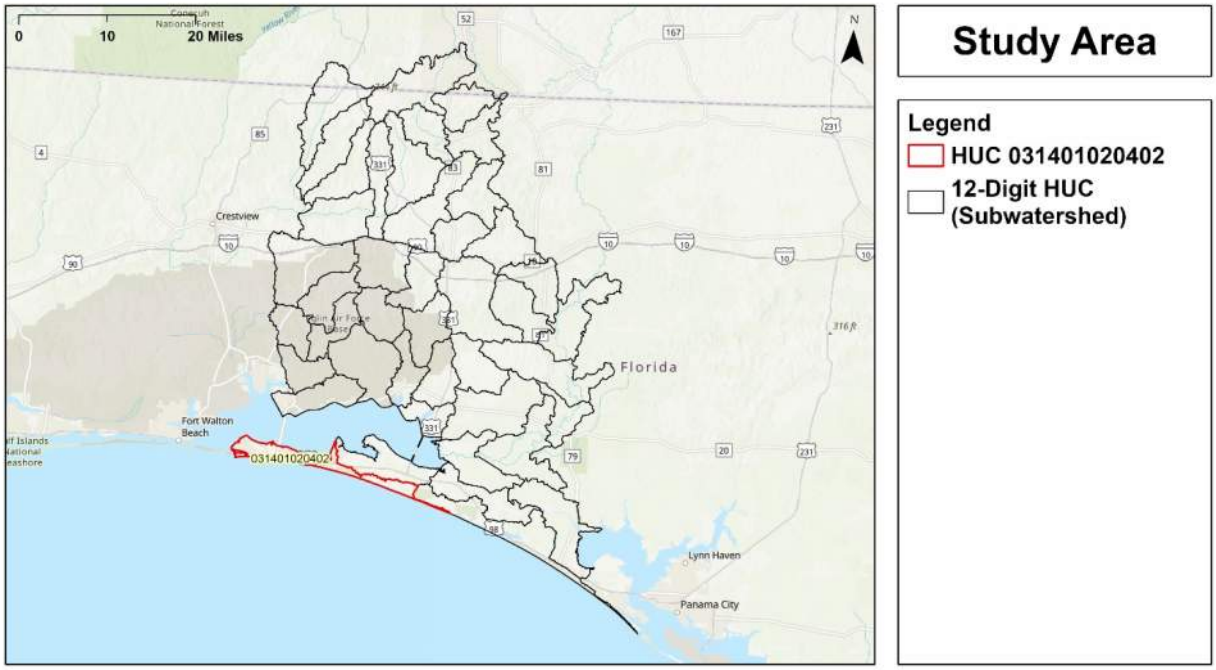

Figure 3. HUC 031401020402 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse

demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in Table 2.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In

order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (Figure 4). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

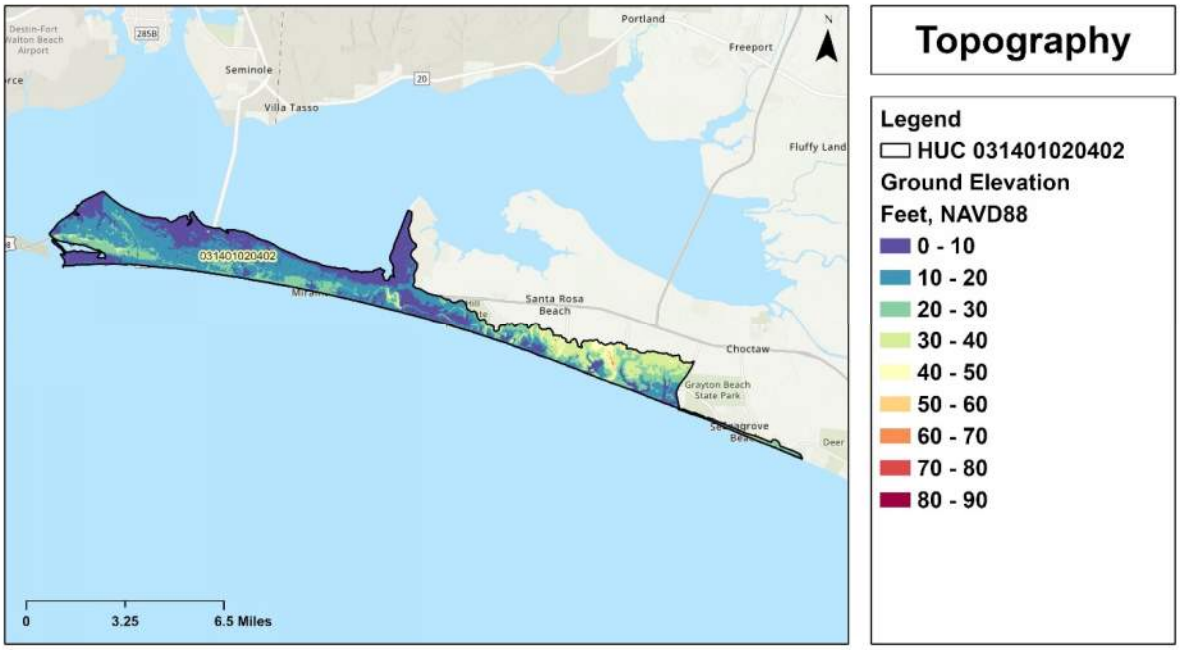

Figure 4. Topographic map of the HUC 031401020402 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020402 sub-watershed is shown in **Error! Reference source not found.**.

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020402 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401020402 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall

biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

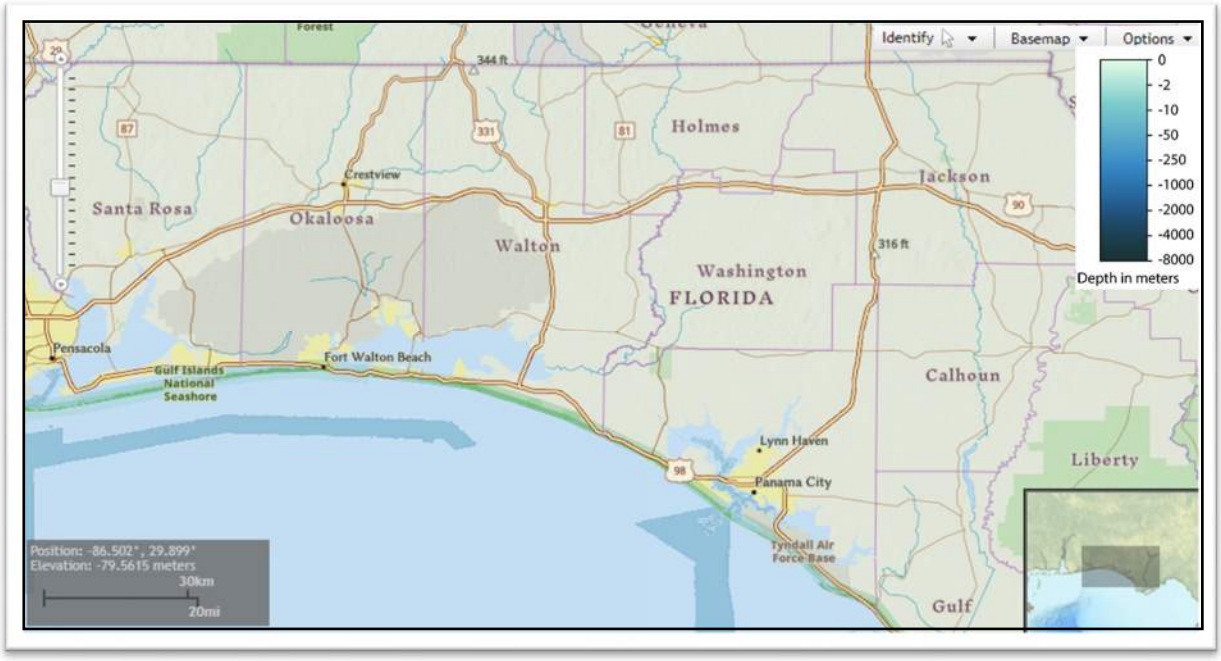

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

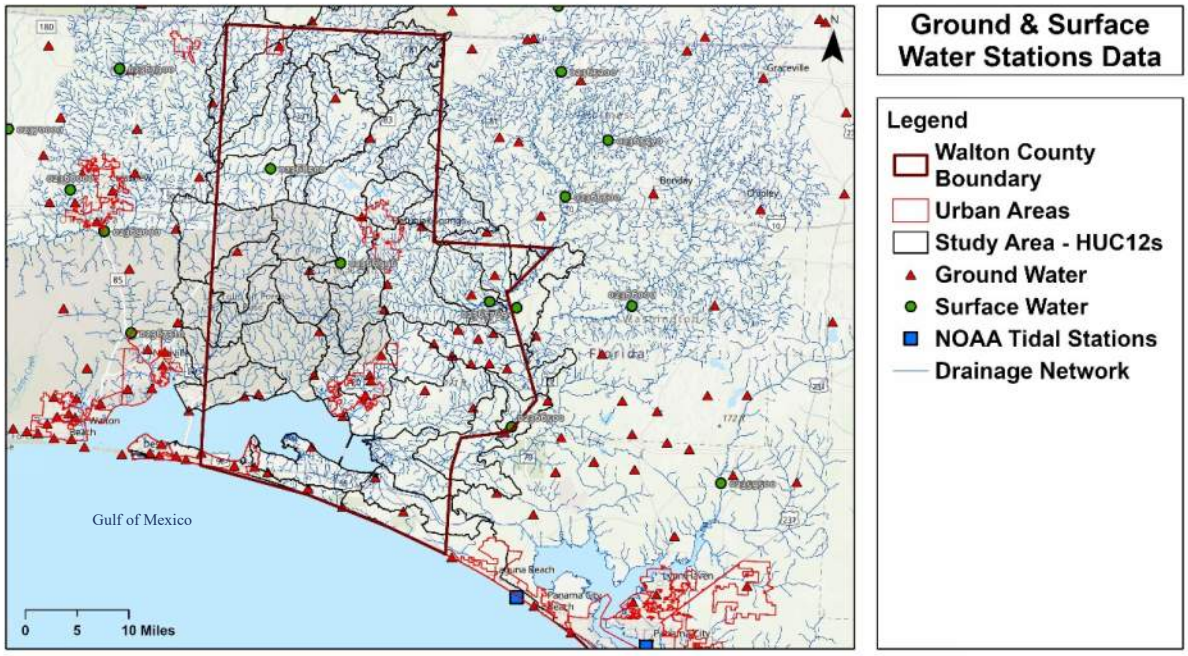

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401020402 is situated between the Gulf of Mexico and Choctawhatchee Bay. There are no other major waterbodies within the basin.

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366500. However, as there are only four surface water station within Walton County, it was necessary to

use the nearest station to the sub-watershed 031401020402, which is USGS 02366500 Choctawhatchee River NR Bruce FLA.

Figure 8. Average streamflow for Choctawhatchee River NR Bruce FLA (USGS 02366500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366500/#parameterCode=00065&period=P365D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides

water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Figure 9 shows the drainage network of HUC 031401020402 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020402 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

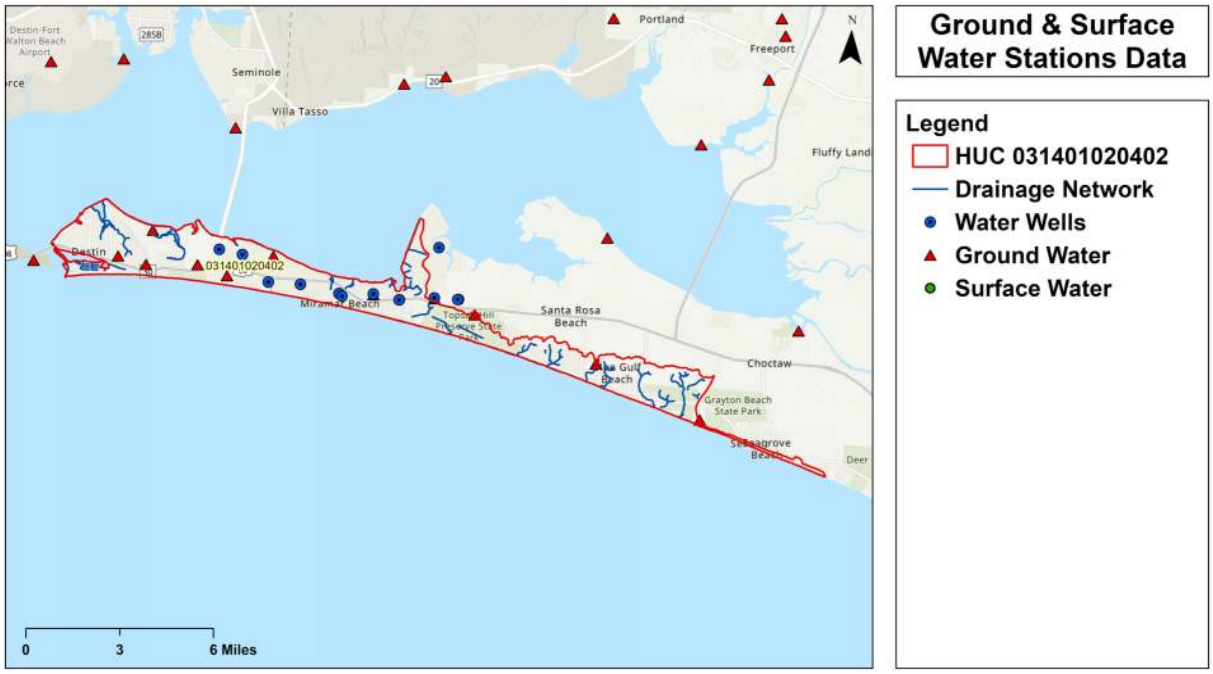

Figure 9. Ground and Surface Water Stations in the HUC 031401020402 sub-watershed, processed by FAU.

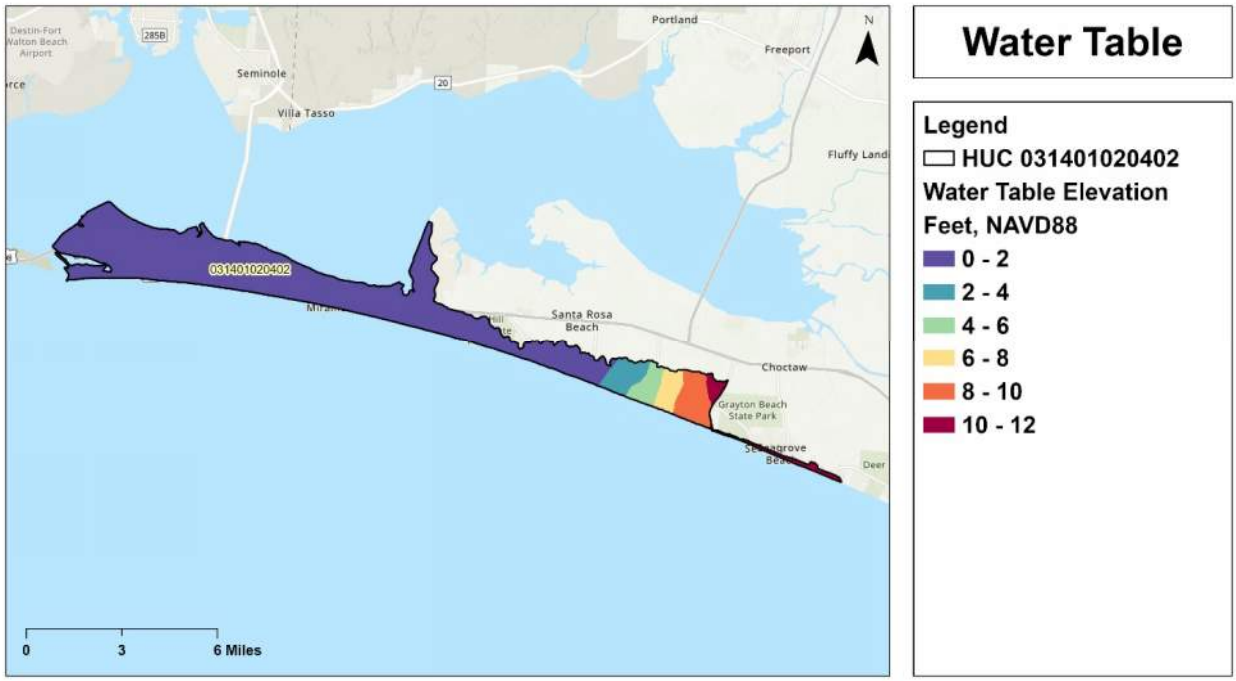

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020402 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

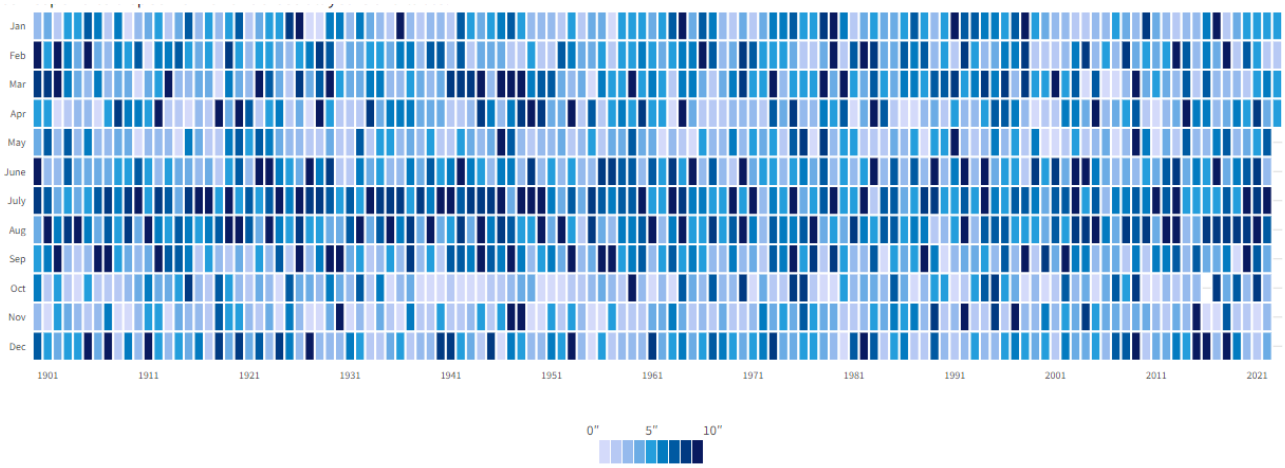

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

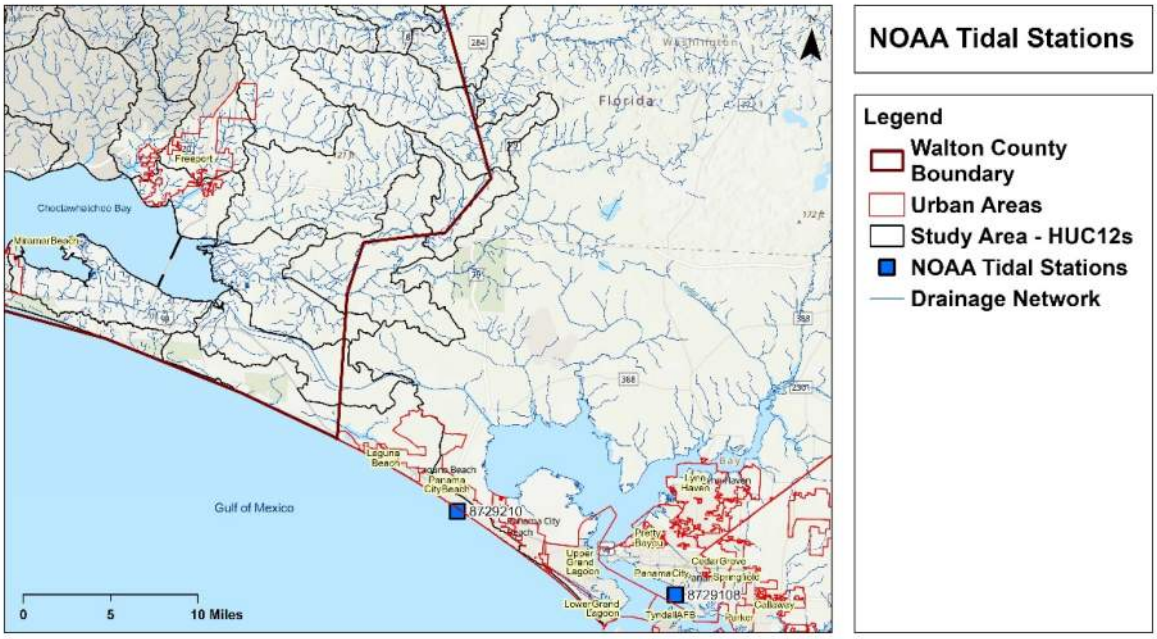

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

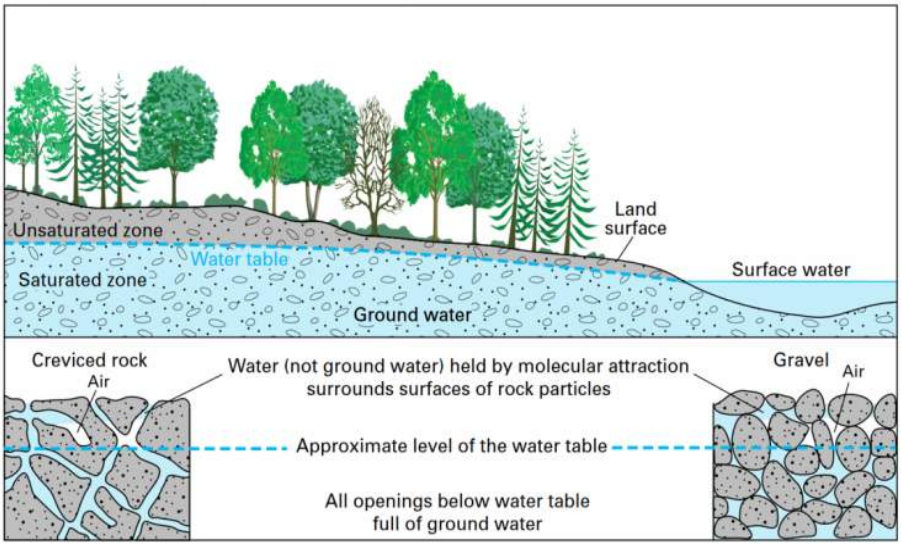

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

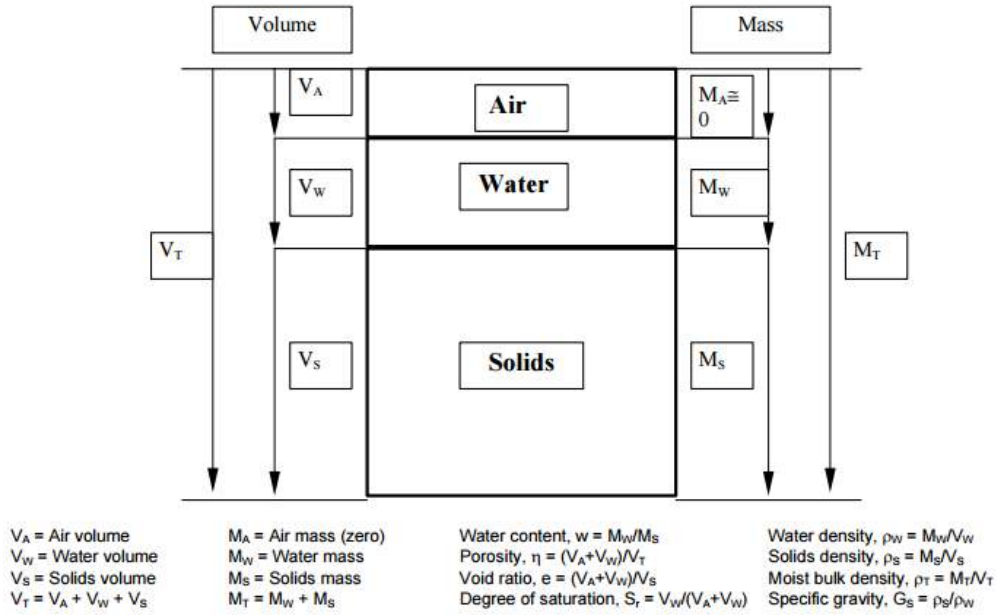

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

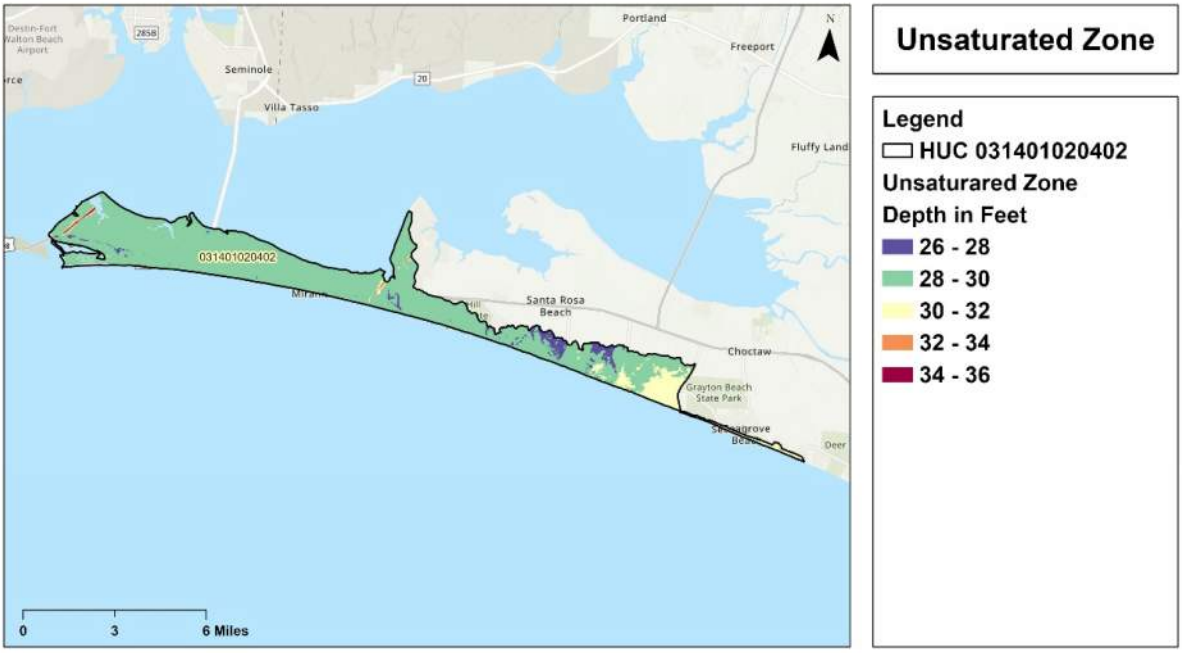

Figure 15. Unsaturated zone map for HUC 031401020402, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A very significant portion of the basin demonstrates a moderately soil storage capacity, falling within the range of 28 to 30 feet of remaining capacity.

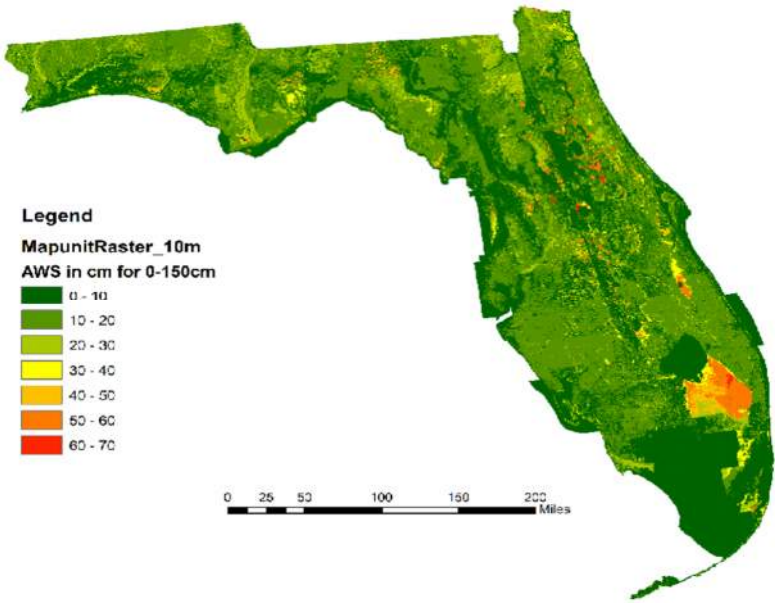

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

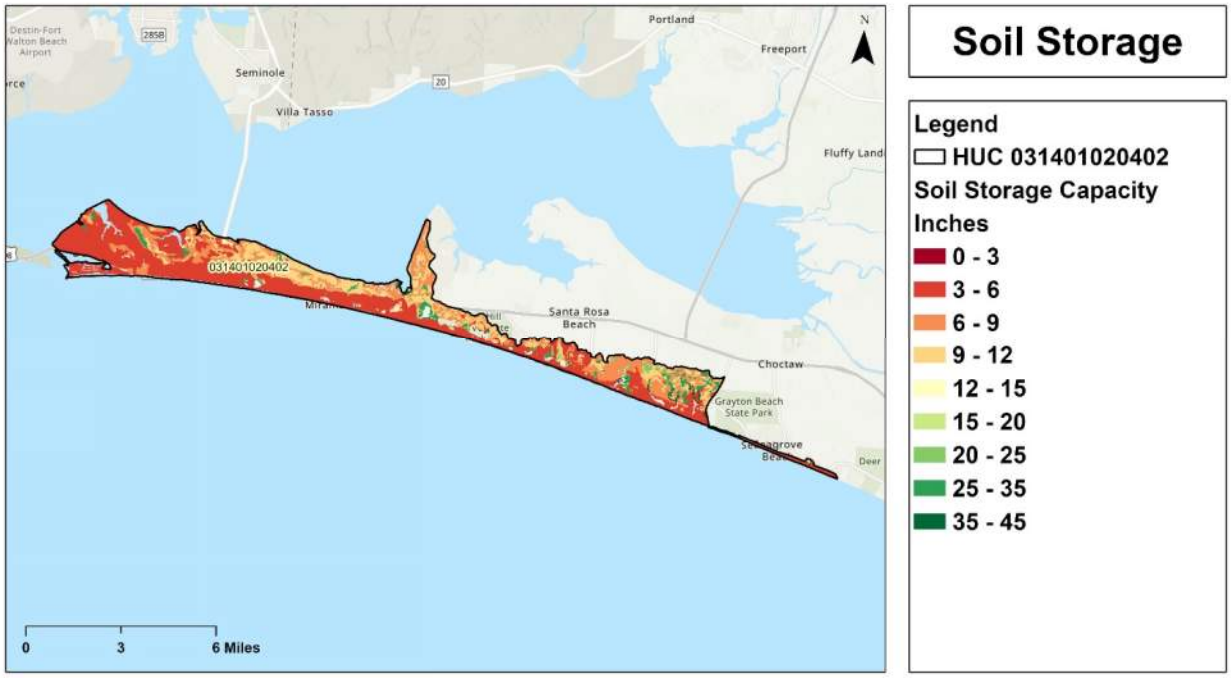

Figure 17. Water storage capacity of soil for the HUC 031401020402, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

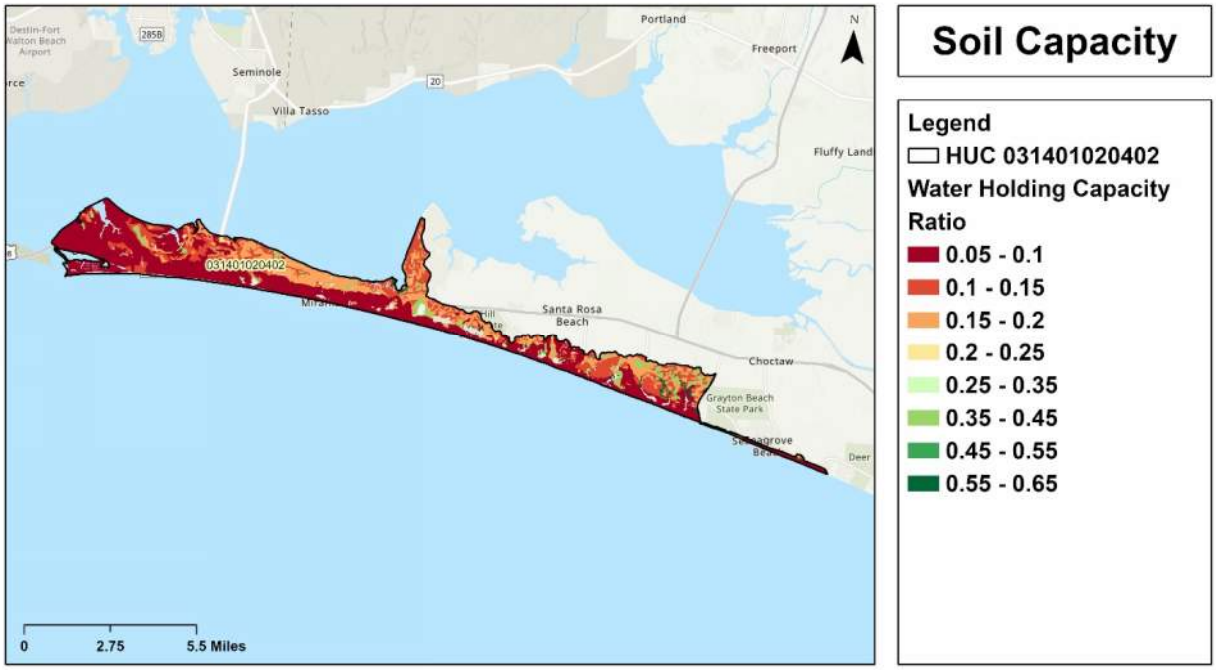

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020402, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

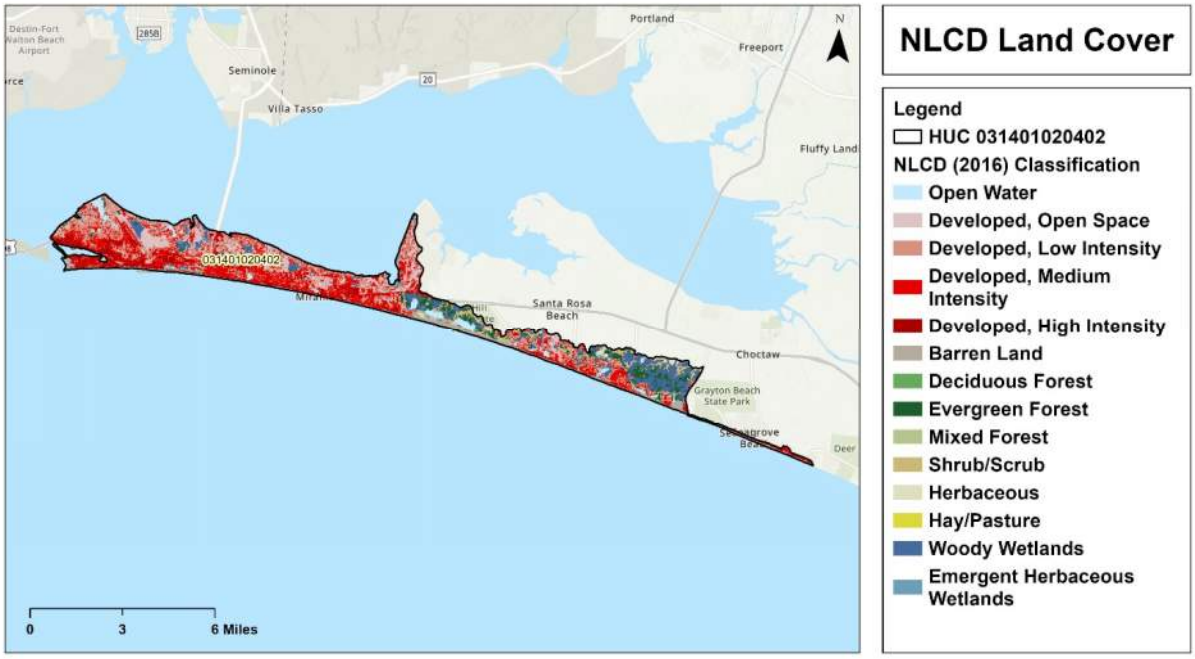

Figure 19. Land use in the HUC 031401020402 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

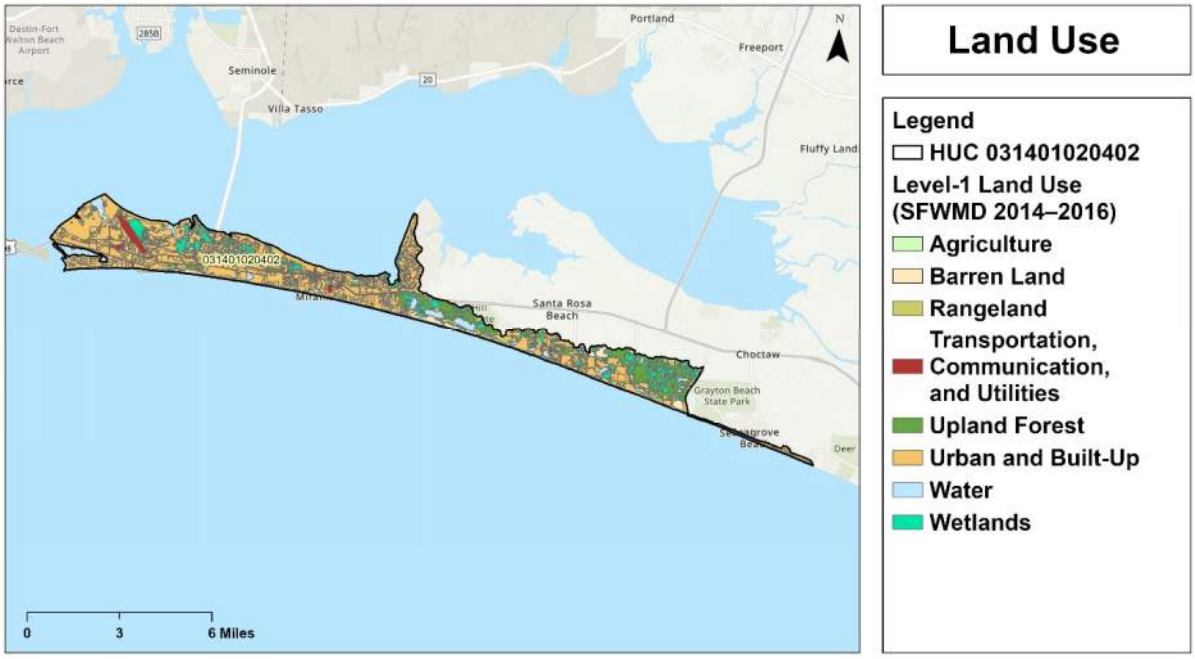

Figure 20. Land use in the HUC 031401020402 (from the 2023 Florida Geographic Data Library (FGDL)), processed by FAU.

In the HUC 031401020402 sub-watershed, the predominant land cover is urban and built-up, accounting for 48.41% of the area. Wetlands comes in second at 14.31%, followed by water at 12.68%, and upland forest at 12.23%, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.It is important to remember that the cities of Destin (outside Walton County's boundary), Miramar Beach and the community of Sacred Oaks are within the HUC's boundary. This is also the more urbanized and populated basin in Walton County.

Table 3. Land use for HUC 031401020402 sub-watershed (2023 Florida Geographic Data Library (FGDL))).

Level 1 Land Use Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	10.49	0.05%
Barren Land	585.74	2.63%

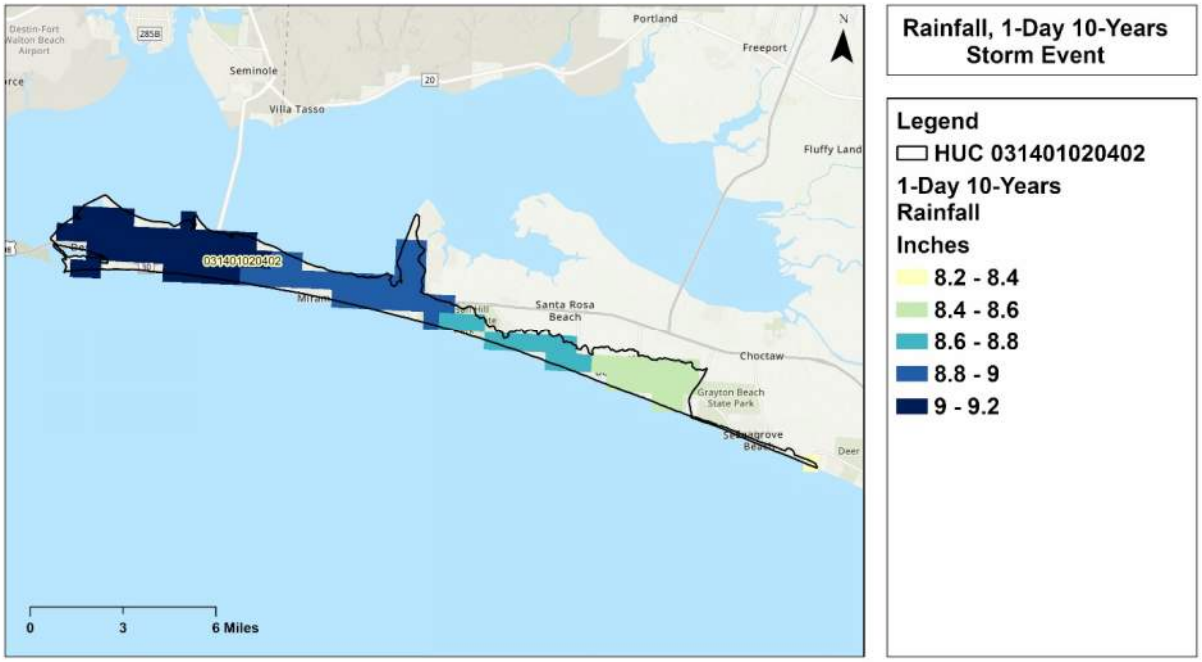

Figure 23. Rainfall distribution map across HUC 031401020402 sub-watershed, for 1-day 10-year storm event, processed by FAU.

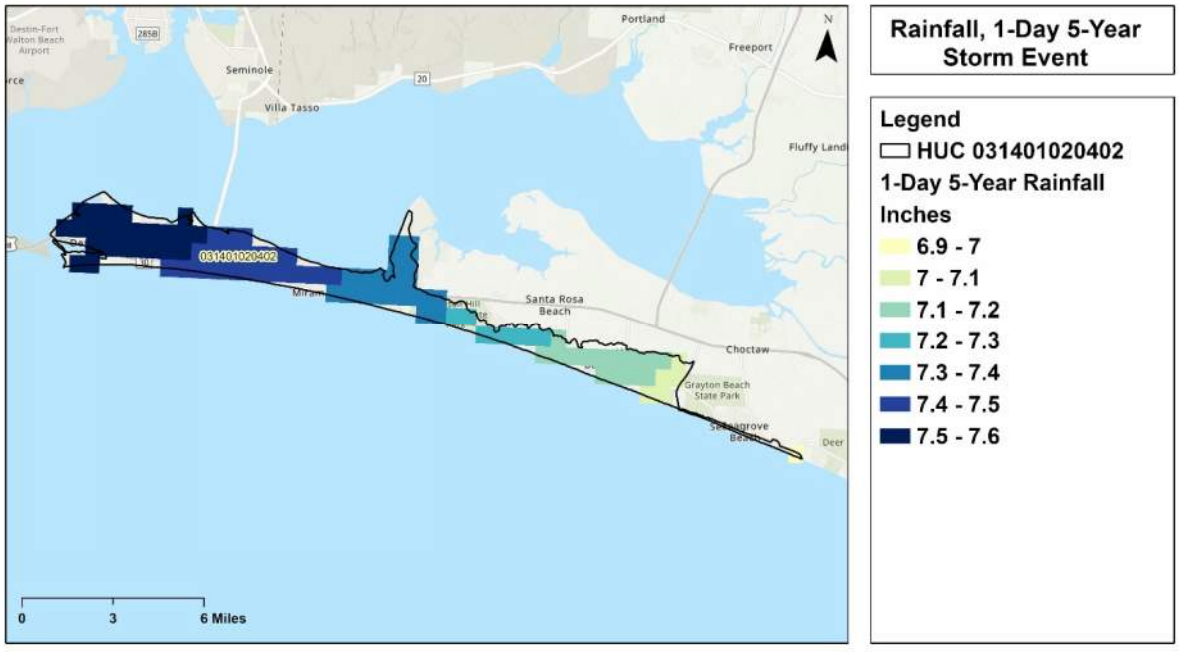

Figure 24. Rainfall distribution map across HUC 031401020402 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically

aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

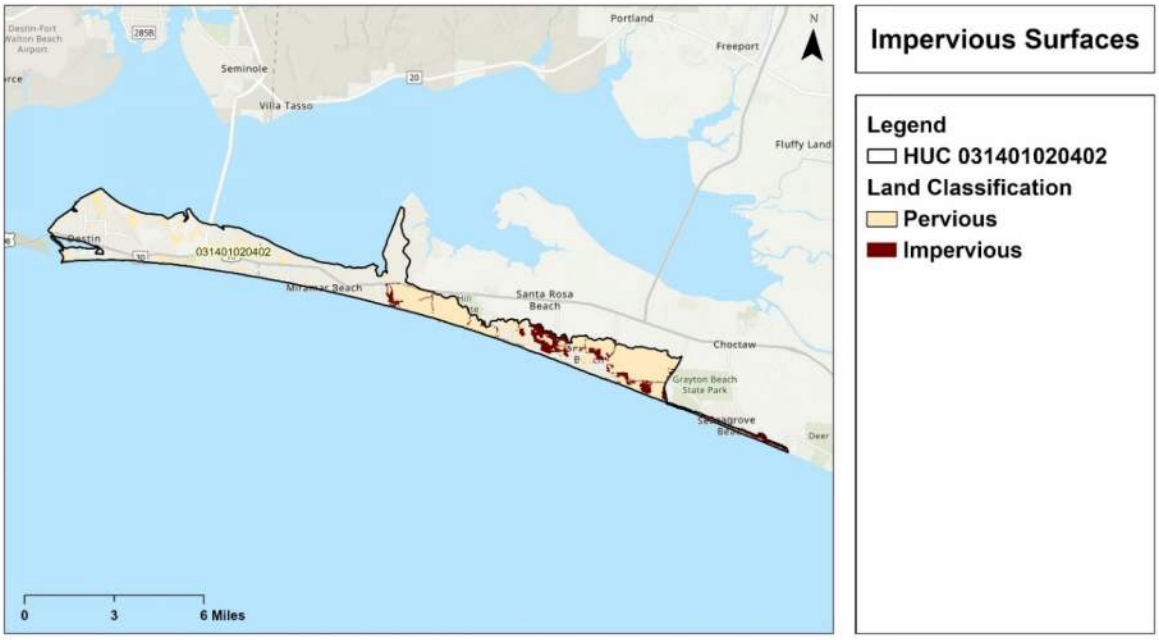

Figure 25. Impervious area map for the HUC 031401020402 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

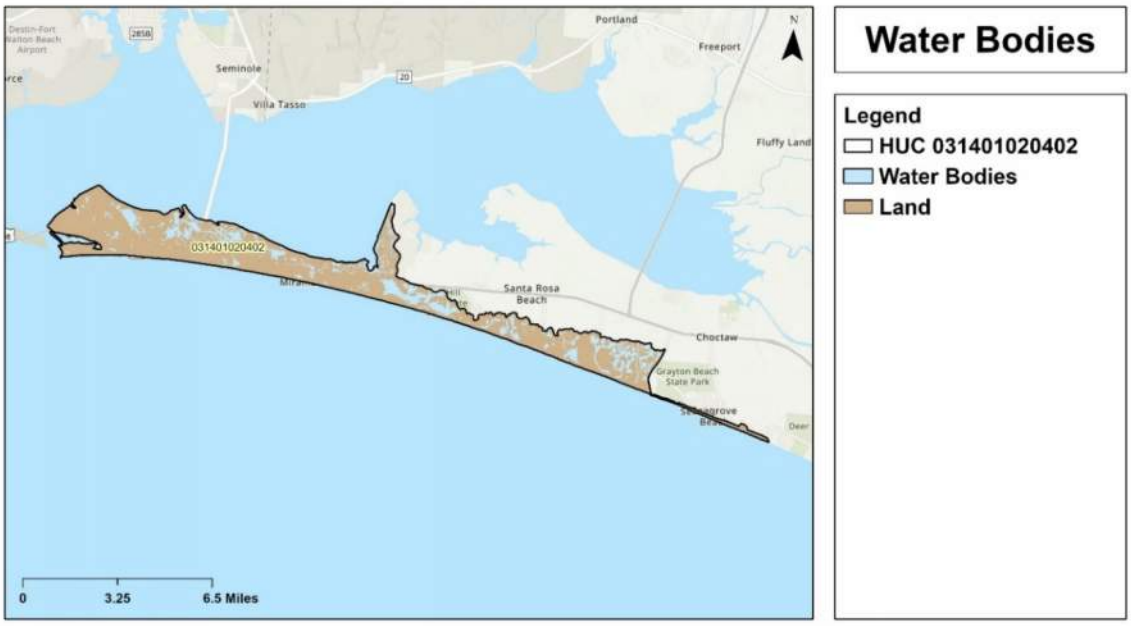

Figure 26. Water bodies map for the HUC 031401020402 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other

waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property. Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Figure 29 presents a zoom in into the drainage structures in Miramar Beach, which is within the basin. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant

control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

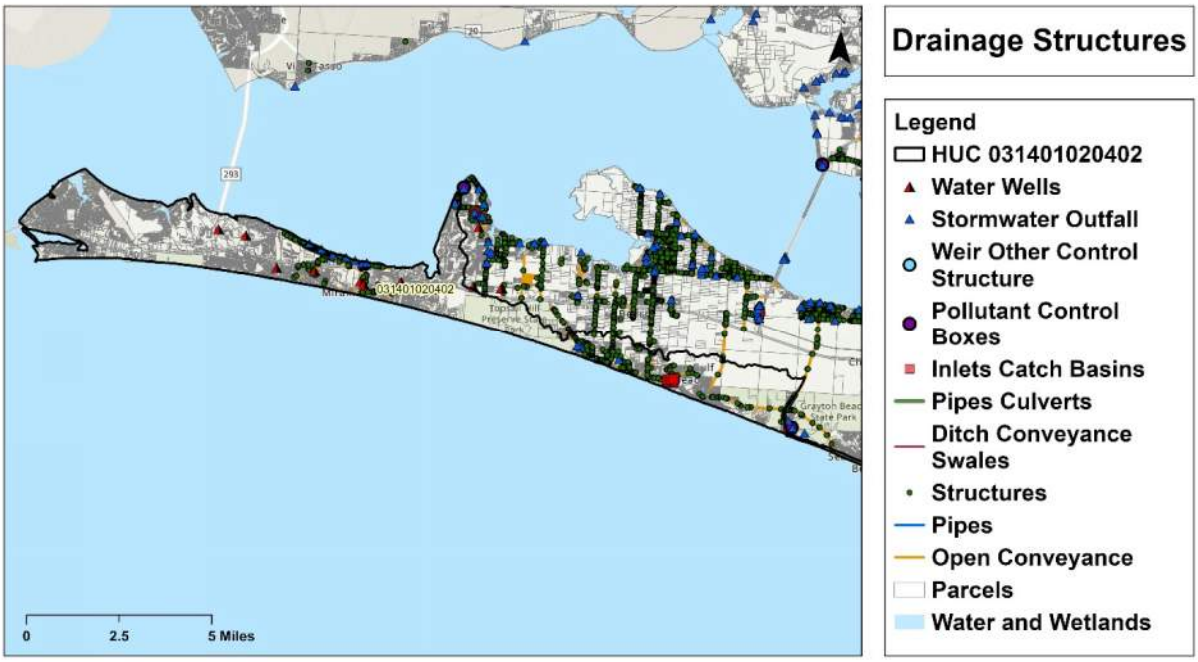

Figure 27. Stormwater Infrastructure for the HUC 031401020402. Processed by FAU.

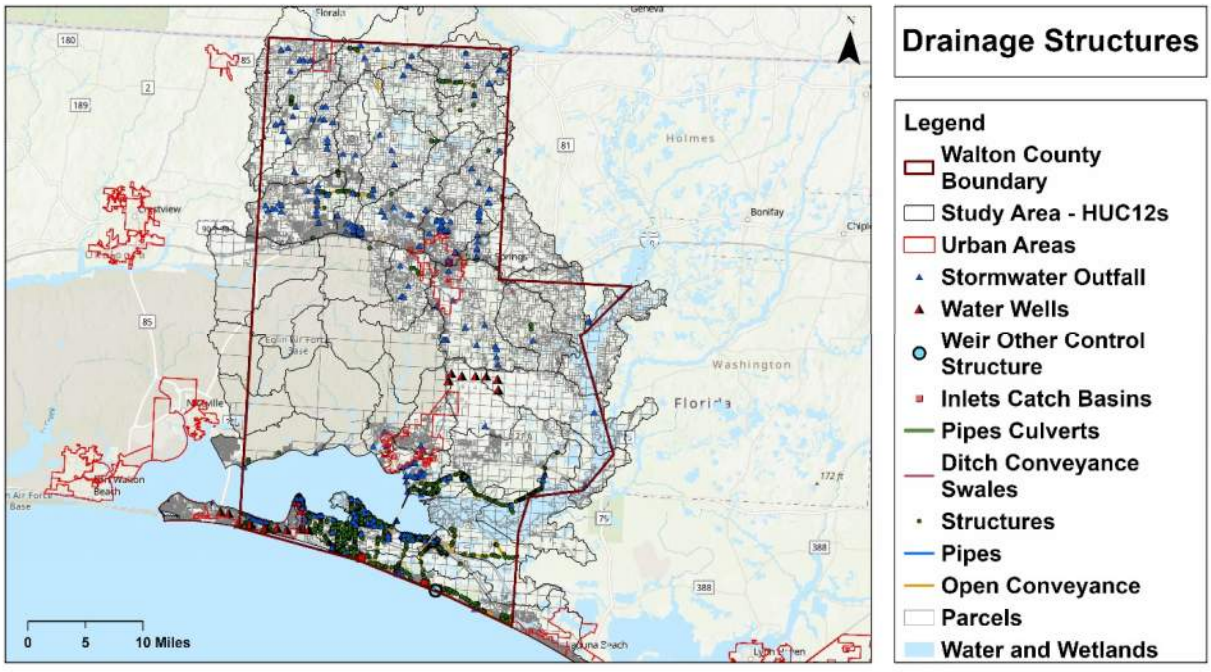

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

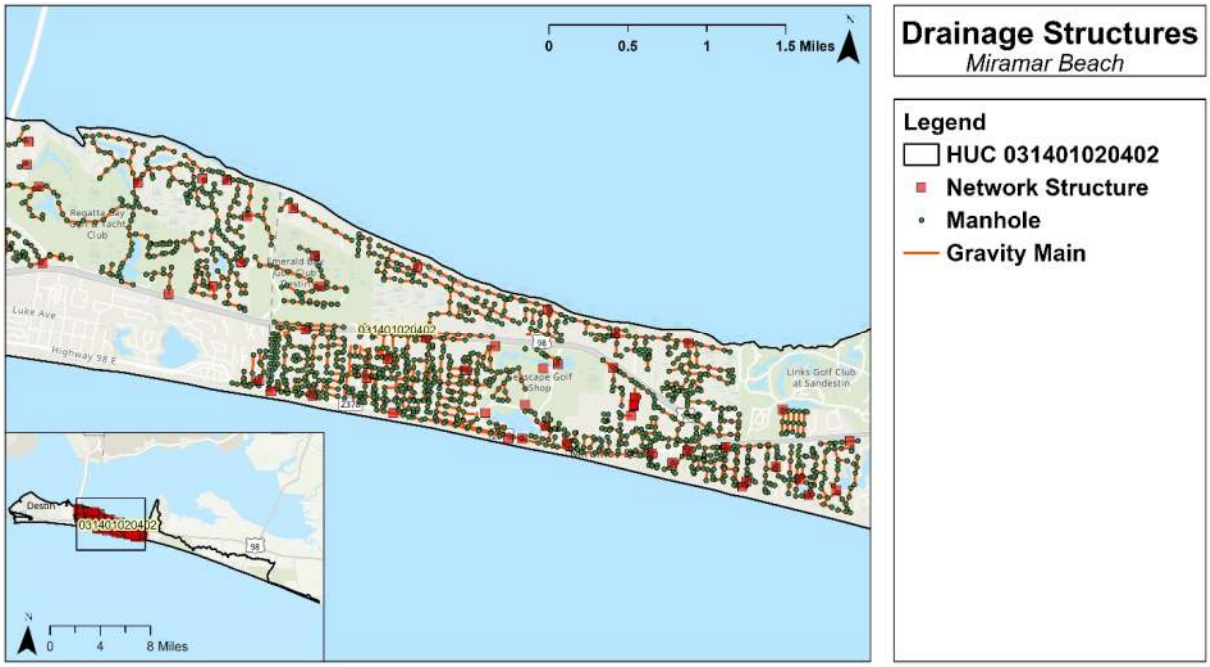

Figure 29. Drainage Structure map for the city of Miramar Beach, processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in Table 5. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020402 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. Figure 30 shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

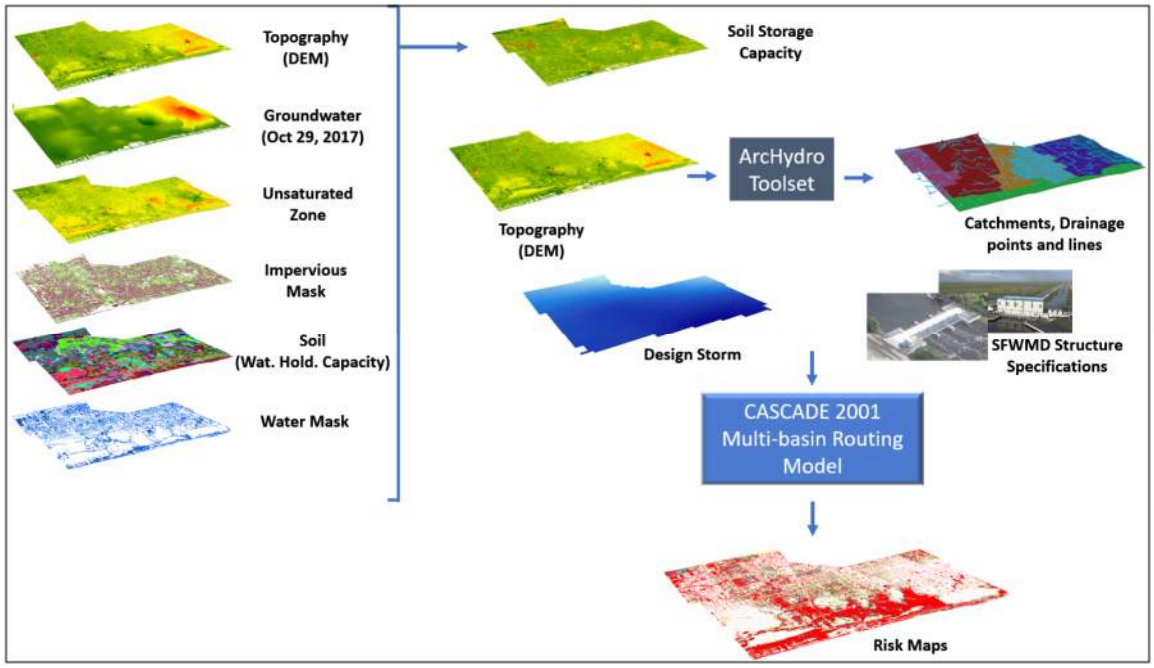

Figure 30. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (Figure 31), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

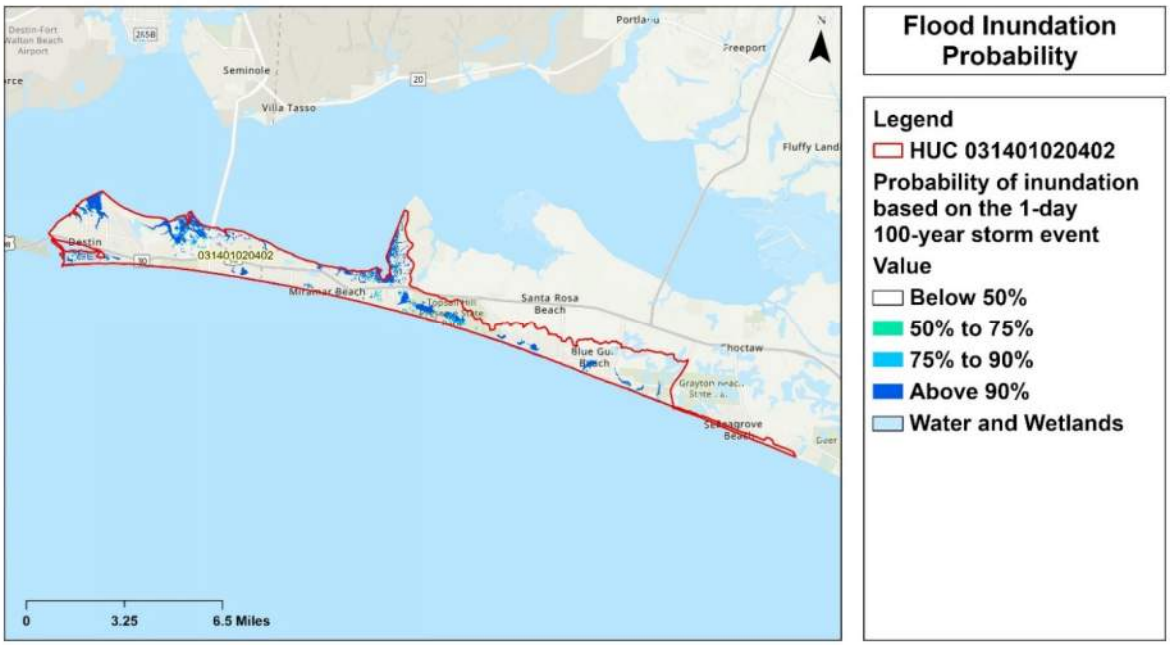

Figure 31. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020402, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA

will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Future Challenges of Sea Level Rise and Climate Change

Global observations from satellites and long-term data collection have made it possible to document and analyze patterns in the Earth's climate. Scientific analysis of the impact of these changes has helped to improve the understanding of future flood hazard driving forces and long-term impacts on human activities and watershed master planning (http://www.research.noaa.gov/climate/t_observing.html). Examples of impacts are rising global average air and ocean temperatures, increased and earlier snow and ice melt, shorter subtropical rainy seasons, shifted seasons, sea level rise and greater variations in temperature and precipitation (IPCC, 2013; Freas et al., 2008; Marshall et al., 2004; Bloetscher et al., 2010). Marshall et al. (2004) specifically focused on the Florida peninsula to predict changes in rainfall and warmer temperatures but interspersed lower low temperatures due to the potential loss of wetlands.

Future changes in climate will add to the existing impacts, at a time when the population of the state is expected to nearly double by 2030. Additional research and high-resolution climate modeling for the Florida peninsula and local jurisdictions is needed to help guide long-term plans like WMPs. Rainfall appears to be decreasing and temperatures rising (see Figure 32).

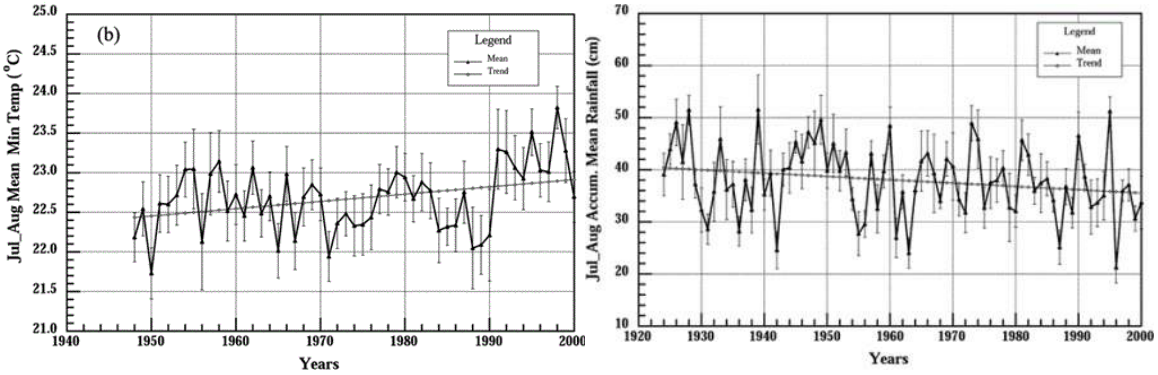

Figure 32. Change in average rainfall and change in average temp 1924 to 2000. Note the reversed trend, which means groundwater input variability is lessened. Source: Marshall et al., 2004.

Climate change is likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly compromised stormwater drainage systems, and d) more frequent inundation of barrier islands and coastal areas.

NOAA and IPCC (2013) predictions suggest that by 2100, global temperatures will be on the order of 2-3°C (3-5°F) higher and sea levels will rise by up to 3 feet. Accompanying these drivers are potential changes in storm frequency and intensity, desertification, population migration, ocean acidification and coastal flooding (IPCC, 2007), exacerbated by the land cover and land use changes, which are substantially impacted by the fluxes, timing and quality of precipitation (Adrians et al., 2003; Scanlon et al., 2005; Marshall et al., 2004; Salmun and Molod, 2006), and leading to changes in the timing of peak flows and volumes (Richey and Costa-Cabral, 2006).

The results of these climatic changes are likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly An outcome of these climatic patterns is that during the past 140 years, an increase in sea levels has been observed (Bloetscher, 2012), a worrying pattern since sea level rise is a permanent phenomenon, that can be catastrophic to low lying areas in the long-term. The question is how much and how soon? Various studies (Bindoff et al., 2007; Domingues et al., 2008; Edwards, 2007; Gregory, 2008; Vermeer and Rahmstorf, 2009; Jevrejeva, Moore and Grinsted, 2010; Bloetscher, 2010, 2011; IPCC, 2007; Heimlich et al., 2009) indicate large uncertainty in projections of sea level rise by 2100. Gregory et al. (2012) note that during the last two decades, the global rate of sea level rise has been larger than the 20th-century time-mean, and Church et al. (2011) suggested that the cause was increased rates of thermal expansion, glacier mass loss, and ice discharge from icesheets. Gregory et al. (2012) suggested that there may also be increasing contributions to global sea level rise from the effects of groundwater depletion, reservoir impoundment, and loss of storage capacity in surface waters due to siltation. Measurements of Florida's east coast (Maul, 2008) show an average rate of sea level rise of 2.27

± 0.04 mm per year from 1915 to 1992 based on tide gauge readings. Analyzing the tidal gauge readings for Florida shows that:

1. Florida average sea level rise is 2.10 ± 0.49 mm/yr
2. All but one location is within the 95% confidence limit range (the exception is Panama City where there is evidence of submergence and other land-based issues)
3. None of the Florida sea level rise rates differ statistically
4. Average global sea level rise for 1920-2000 was 2.0 mm/yr – within 95% confidence limit for Florida locations

From 1929 to 1992, over eight inches of sea, with another 6 inches added since 1992, which is already having significant impacts on coastal communities where population growth has increased the need for improved flood management strategies (Bloetscher, 2008; Parkinson, 2010; Zhang et al., 2011, 2011a; NFIP, 2011; Schmidt et al., 2011; Warner et al., 2012).

As a result, the SFRCCC (2015) adopted USACE's methodology to derive scenarios of sea level change intermediate to high rates of sea level rise for years 2030 (3" to 7") and 2060 (9" to 24") as the consensus projection to guide future planning. The path keeps increasing – now 14 inches since 1929 (Figure 33) caused by thermal expansion of the ocean and melting ice caps (Jevrejeva et al., 2010; Vermeer and Rahmstorf, 2009). Sea level rise is a major concern in Florida, including Walton County, since the majority of the state's population live on the coast, involving most major commercial, residential, and economic enterprises. Figure 33demonstrate the estimated sea level change for Panama City, considering the predictions of NOAA 2017. For NOAA high scenario SLR change scenario, the estimated level change is higher than 8 ft., while for the intermediate and low scenarios are about 3.9 feet and 1.7 feet respectively.

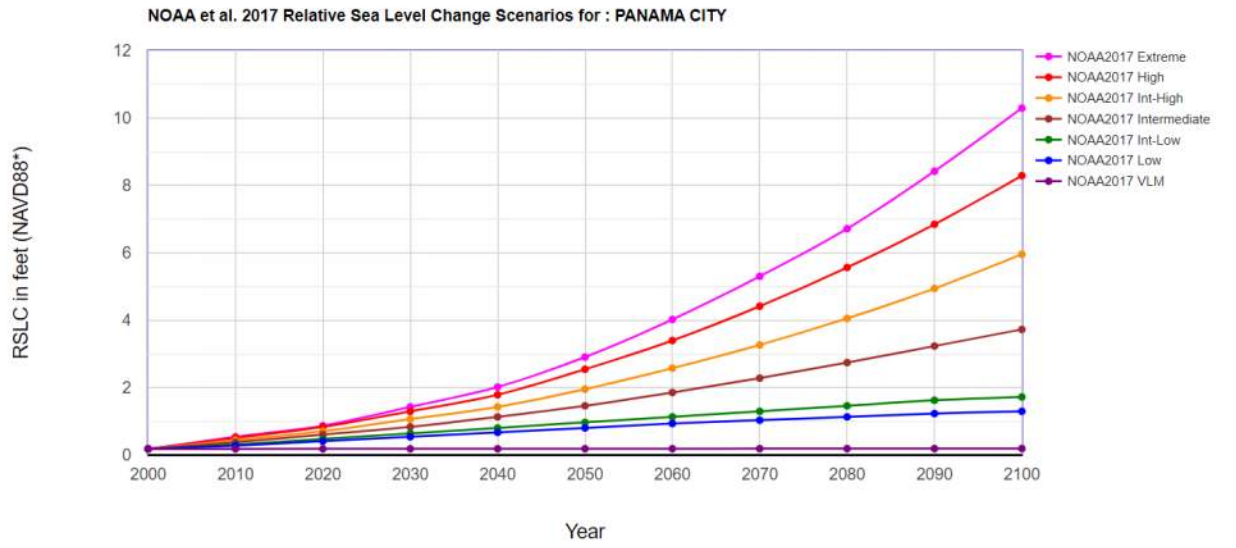

Figure 33. Relative Sea Level Change Scenarios for gauge 8729108, Panama City, FL. Source: NOAA 2017 (https://cwbi-app.sec.usace.army.mil/rccslc/slcc_calc.html)

NOAA (2017) outlines five scenarios for sea level rise. The NFIP proposes the use of the intermediate high projection, which is 1.2 meters or 4 ft globally from current sea level elevations (Figure 34).

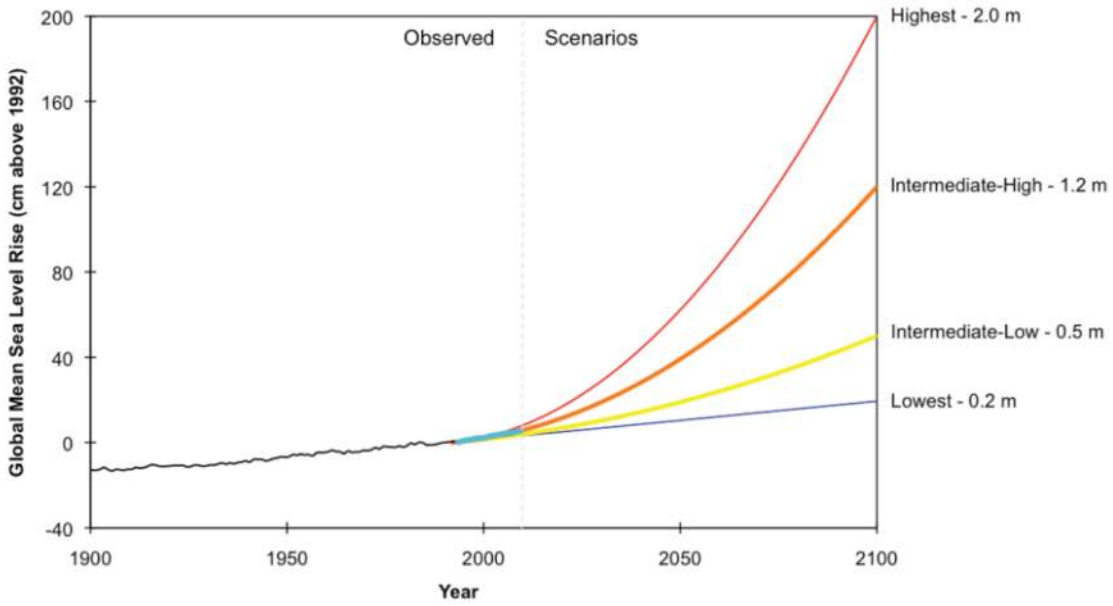

Figure 34. Graphic of global sea level rise projections from NOAA (2017). Source:https://tidesandcurrents.noaa.gov/publications/techrpt83_Global_and_Regional_SLR_Scenarios_for_the_US_final.pdf

As sea level rises, access to roads, bridges, rail, and transit could be at risk of flooding, causing the effects of sea level rise to spread indirectly throughout the entire transportation network, affecting the overall system performance. For example, the flooding of a critical road or facility access can cause a shifting of traffic flow causing congested conditions in other roadways that are not actually flooded. Since the roadway network would be unable to carry the traffic demand, the system would experience operational failure; as a result, causing travel times and delays. Moreover, the inundation of a critical access could cause transportation connectivity problems to essential infrastructure like ports or airports. Transportation infrastructure relies on the effectiveness of flood control and stormwater drainage systems for the transportation corridors. Road integrity relies on adequate drainage. The increased risk of severe flooding in Florida's low-lying terrain can adversely affect transportation infrastructure along the coastline; roads can be inundated, and roadway beds can be damaged. Sea level rise will cause increased water table levels (FDOT, 2012), as regional water tables cannot exist naturally below mean high tide (2 feet in Florida). Adding 3 feet of sea level rise on top of groundwater would compound the risk of flooding in low-lying areas. Road bases below 5 feet NVGD would become saturated under this scenario, likely causing premature base failure. As soil storage capacity is diminished due to rising

groundwater elevations associated with sea level rise, the potential for more frequently flooded roadways would likely damage pavements (FDOT, 2012). Hence sea level rise must be accounted for in WMPs in coastal areas. To allow flexibility in the analysis due to the range of increases within the different time periods, an approach that uses incremental increases of 1, 2, and 3 feet of sea level rise is suggested for modeling. The increments can work as threshold values in planning considerations in terms of allowing planners the ability to know ahead of time where the next set of vulnerable areas will be, to allow for a proactive response approach that can be matched to the observed future rates. Sea level rise is a major concern since nearly half the US population lives within 50 miles of the coast, involving most major commercial, residential, and economic enterprises. The effects of 5 ft sea level rise, King tide, and 1-day 100-year storm event are shown in Figure 35.

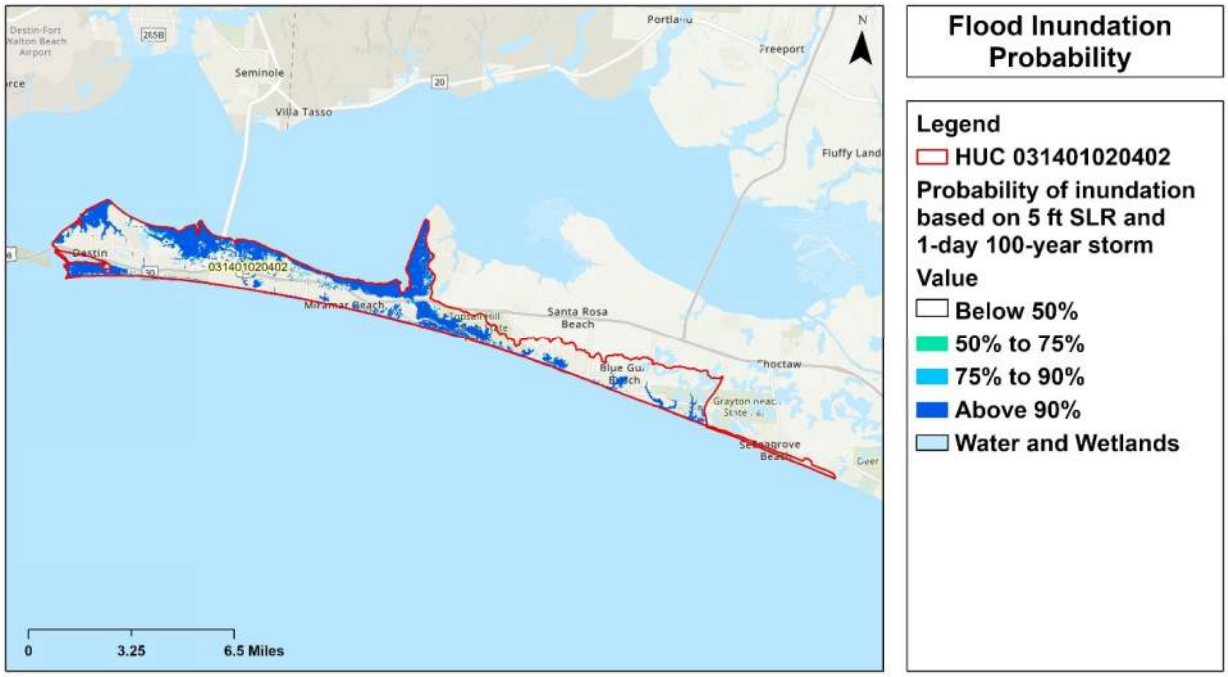

Figure 35. Flood Inundation Probability for a Sea level rise of 5 ft + 1-day 100-year storm event for HUC 031401020402 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Dark blue is area under 5 ft NAVD88 and potentially inundated at the 99th percentile tidal conditions. Processed by FAU.

2.4 Modeling Results

Figures 36-59 are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. **3-day 25-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 36)
2. **1-day 100-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 37)
3. **1-day 10-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 38)
4. **1-day 5-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 39)
5. **Sea level rise of 1 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 40)
6. **Sea level rise of 1 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations storm (Figure 41)
7. **Sea level rise of 1 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 42)
8. **Sea level rise of 1 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 43)
9. **Sea level rise of 2 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 44)
10. **Sea level rise of 2 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 45)
11. **Sea level rise of 2 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 46)
12. **Sea level rise of 2 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 47)
13. **Sea level rise of 3 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 48)
14. **Sea level rise of 3 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 49)

15. **Sea level rise of 3 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 50)
16. **Sea level rise of 3 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 51)
17. **Sea level rise of 4 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 52)
18. **Sea level rise of 4 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 53)
19. **Sea level rise of 4 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 54)
20. **Sea level rise of 4 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 55)
21. **Sea level rise of 5 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 56)
22. **Sea level rise of 5 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 57)
23. **Sea level rise of 5 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 58)
24. **Sea level rise of 5 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 59)

In all scenarios, a considerable amount of flooding is noted along the coast and, following the waterbodies flow path. As this basin connects to the ocean though the Gulf of Mexico and Choctawhatchee Bay, SLR scenarios plays an important hole, implying a considered growth as the projected scenario of rising tides rises.

The design storm simulation determined that approximately 13.8% of the HUC total area or 3.73 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 14.2% of the HUC's total area, or 3.84 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 13.3% of the HUC's total area,

or 3.59 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 13% of the HUC's total area, or 3.51 mi², would be expected to be inundated during the 1-day 5-year storm. Table 7 compares the four storm events.

Table 7. HUC 031401020402 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	23.30	3.73	86.2%	13.8%
1-day 100-year	23.19	3.84	85.8%	14.2%
1-day 10-year	23.44	3.59	86.7%	13.3%
1-day 5-year	23.51	3.51	87.0%	13.0%

2.5 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.5.1 Results

Figure 60 to Figure 62Figure 62 depict the HUC 031401020402 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (Figure 60) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 61) overlays critical facilities onto the 1-day 100-year storm event scenario, while the third map (Figure 62) represents the same overlay within the context of 5 feet of sea level rise (SLR) combined with the 1-day 100-year storm event. Figure 63 is a mosaic showing critical facilities overlaid in the 5 feet SLR + 1-day 100-year storm event for the whole county.

Additionally, Figure 64 and illustrate the composite score for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Figure 65 represents the calculation for composite score based on 1-day 100-year storm event, while **Error! Reference source not found.** shows the calculation for composite score for the same storm event, but including a 5 feet of Sea Level Rise scenario. Figure 66 shows the same area zoomed out.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.5.2 Drill-down – Miramar Beach and Sacred Oaks

For enhanced visualization of the urban areas within this HUC 031401020402, the following maps illustrate the same results for critical facilities (land use priorities) and composite scores, but on a reduced scale, which better facilitates the examination of finer details within the urban area (Miramar Beach and Sacred Oaks). These maps cover both the 1-day 100-year scenario and the 1-day 100-year + 5 feet SLR scenario. Figure 67 to Figure 81 show drilldowns into the community – starting with priority of land uses, composite scores and flooding (in set of 3).

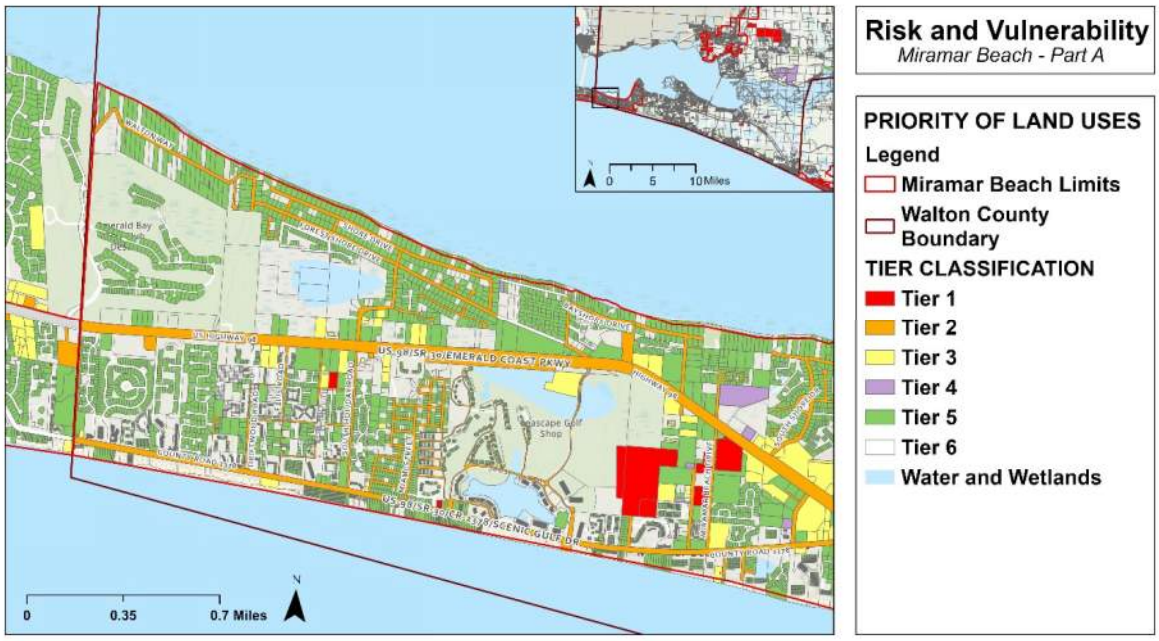

Figure 67. Critical Facilities (priority of land uses) map for Miramar Beach (part A). Processed by FAU.

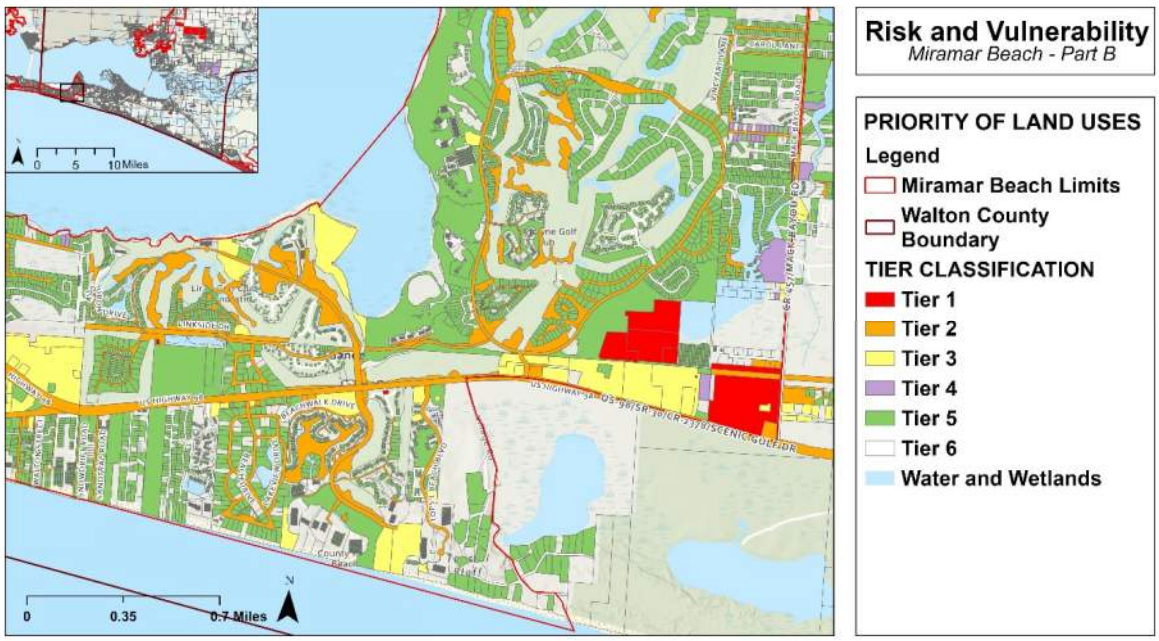

Figure 68. Critical Facilities (priority of land uses) map for Miramar Beach (part B). Processed by FAU.

2.5.3 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020402. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.5.4 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020402. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020402	17299.39
All of the 1-day 100-year storm event inundation	**2457.96**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	465.76
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	176.24
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	1992.20
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	1815.96

2.5.5 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. Figure 82 indicates the results

from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

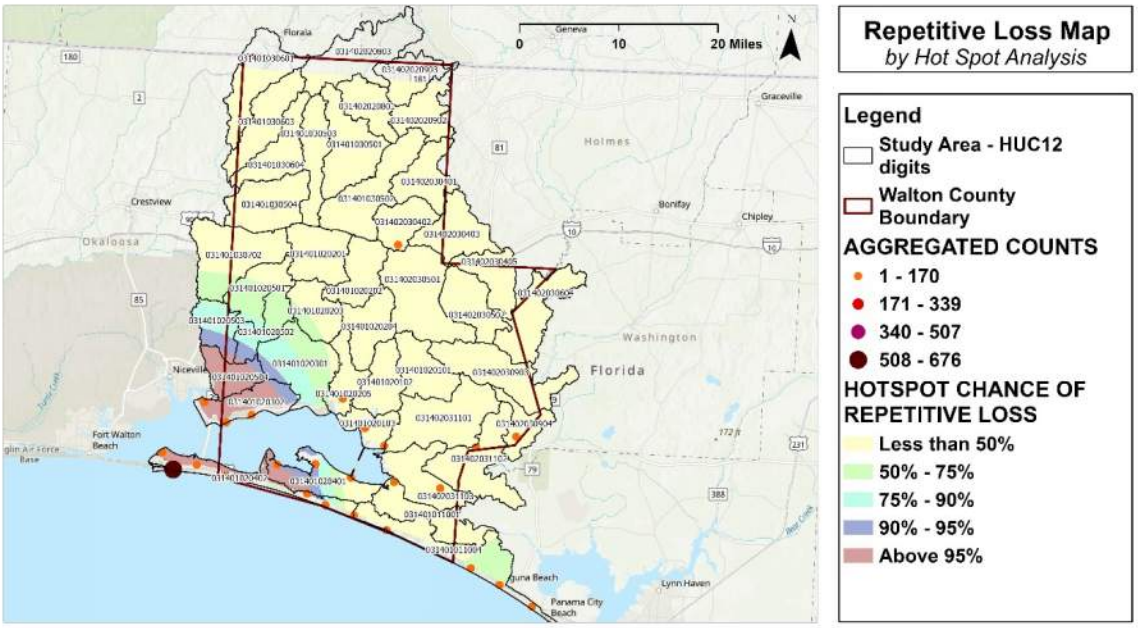

Figure 82. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.5.6 Priority Projects

The basin encompasses Miramar Beach, the most densely populated area in the county, characterized by medium-to-high development. Unfortunately, a significant portion of this community faces a severe flooding risk, particularly during a 1-day 100-year storm event + 5 ft. SRL scenario. The basin's coastal location, resembling a peninsula, renders all sides vulnerable to rising tides and sea-level increases. The alarming frequency of flooding in both scenarios highlights the urgent need for intervention.

Regarding land use priority, numerous critical facilities fall within the flood zone, including 51 parcels classified as tier 1. However, not all of these tier 1 parcels are within the flood-prone areas. The basin displays a diverse range of land use priorities, covering tiers 2 to 6, totaling 35,600 parcels. A substantial proportion of these parcels are affected by flooding, particularly when considering the 5 feet of sea-level rise scenario.

An in-depth analysis of the composite score offers a detailed view of parcels within the flood zone. A total of 341 parcels face the impact of the 1-day 100-year storm event + 5 ft. SRL scenario, with 184 parcels affected solely by the 1-day 100-year storm event.

In the most critical scenario (1-day 100-year storm event + 5 ft. SRL), 105 parcels fall within the score range of 5-6, signifying the highest priority for intervention. These include three utility parcels, two public schools, one college, one financial institution, and all the remaining parcels are roads, such as W Shipwreck Rd, Shore Drive, Linkside Dr, Prestwick Pl, North Geronimo Street, Burnt Pine Ln, Walton Way, Audubon Drive, Sandestin Blvd West, Lake Point Drive, and Del Mar Ct.

Within the score range of 4-5, 48 parcels are identified, encompassing a community shopping center, seven office buildings, eight restaurants/cafeterias, two hotels, one light manufacturing facility, one public school, one hospital, seven utility parcels, and the rest are roads, including County Highway 30a, South Shore Dr, Forest Shore Drive, Beach Drive, Walton Way, Bayshore Drive, Lakeview Drive, Thompson Drive, Open Gulf Street, and Stallworth Blvd.

The score range of 3-4 encompasses 182 parcels, featuring 23 mobile homes, five regional shopping centers, 13 community shopping centers, 32 office buildings, four professional service buildings, 25 restaurants/cafeterias, two repair service shops, two auto sales/auto repair facilities, 11 hotels, one light manufacturing facility, one private school, two privately owned hospitals, one homes for the aged, one orphanage, and all remaining parcels are roads, including portions of County Highway 30a, US Highway 98, Allen Loop Road, County Road 2378, Eastern Lake Road, Overlook Drive, Sandtrap Road, and Tops'l Beach Blvd.

Lastly, seven parcels receive a score "below 3" based on the composite score classification. These comprise five mobile homes and two orphanages or other non-profit organizations.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020501) is highlighted among all the HUCs to help identifying its location. (Figure 3).

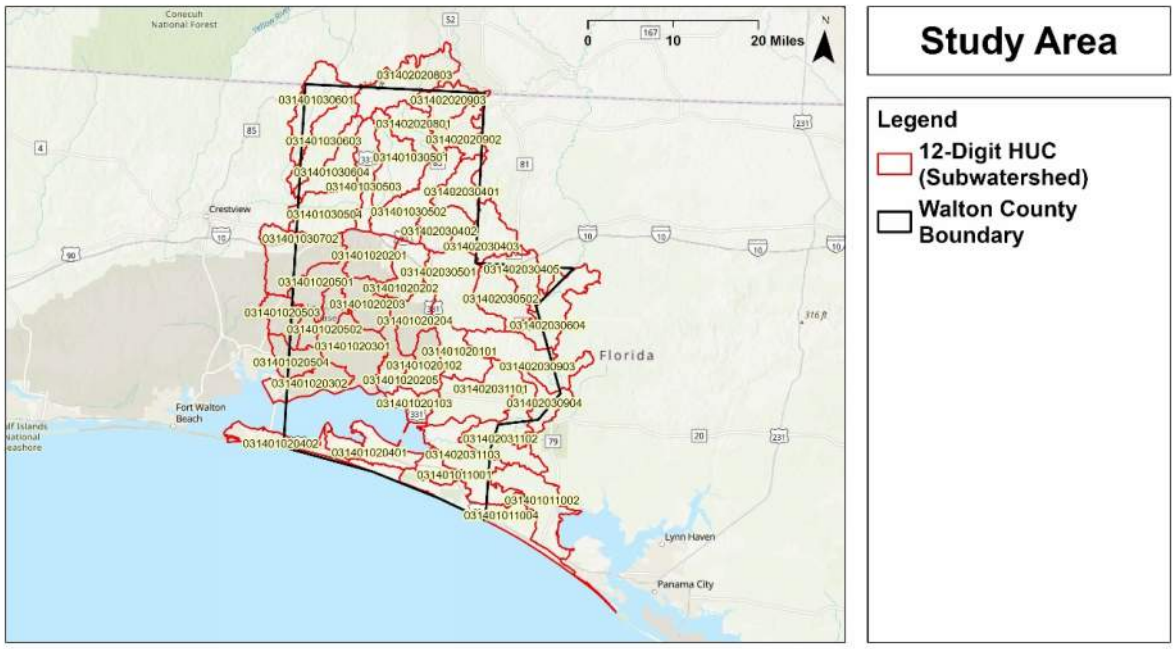

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

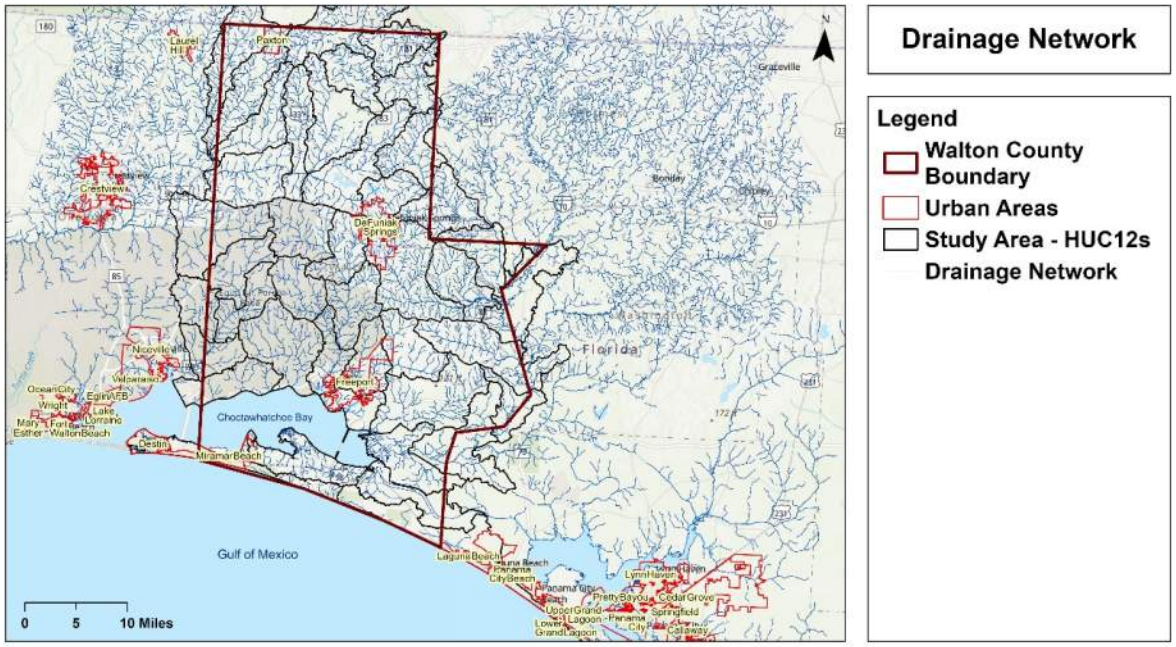

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

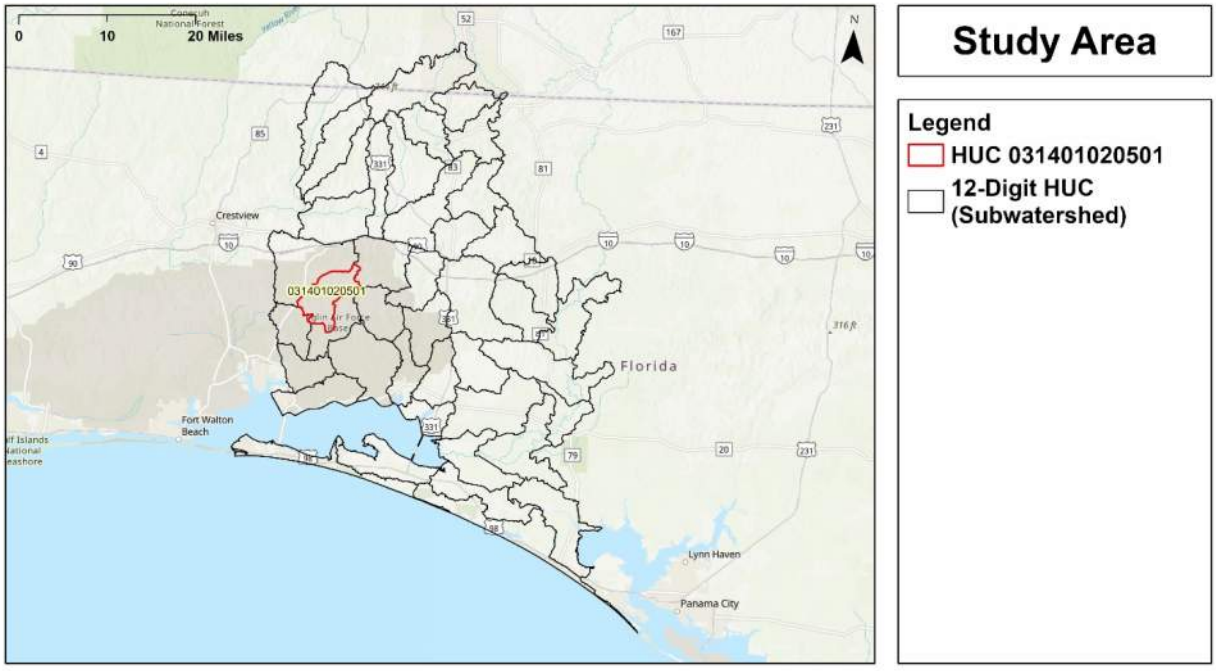

Figure 3. HUC 031401020501 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development, tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

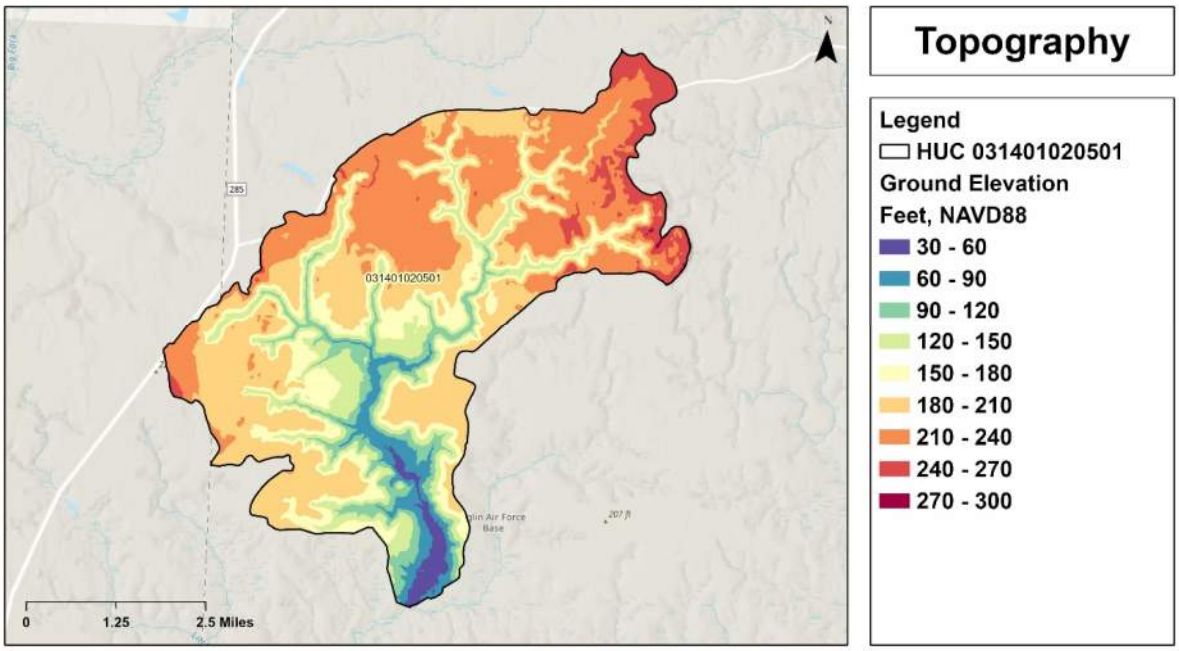

Figure 4. Topographic map of the HUC 031401020501 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020501 sub-watershed is shown in **Error! Reference source not found.**.

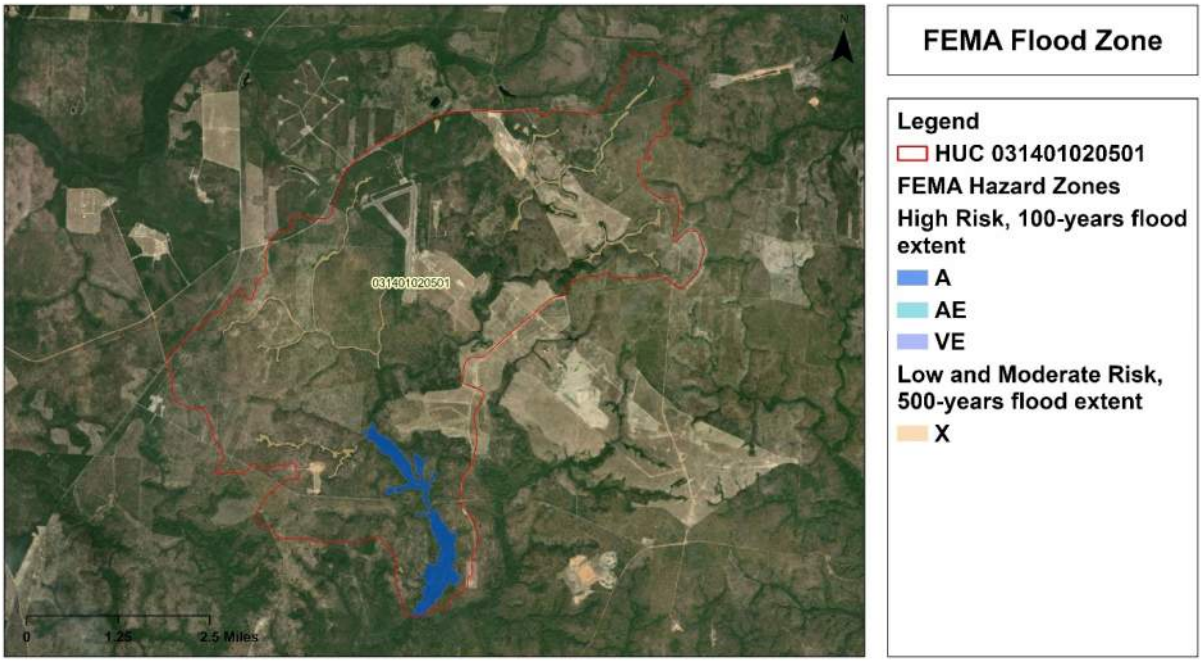

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020501 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401020501 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

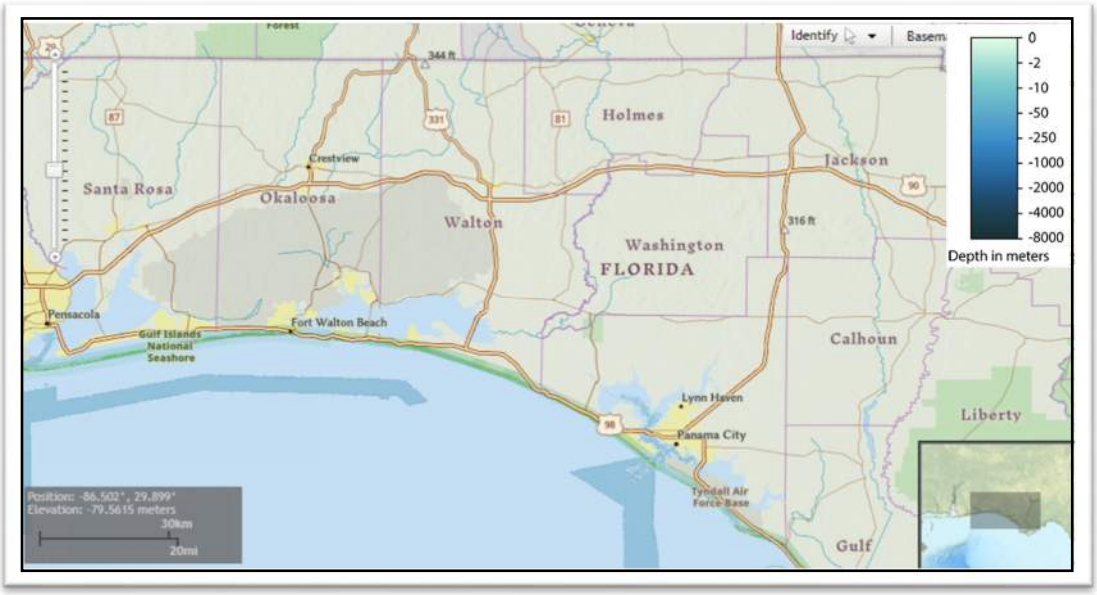

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

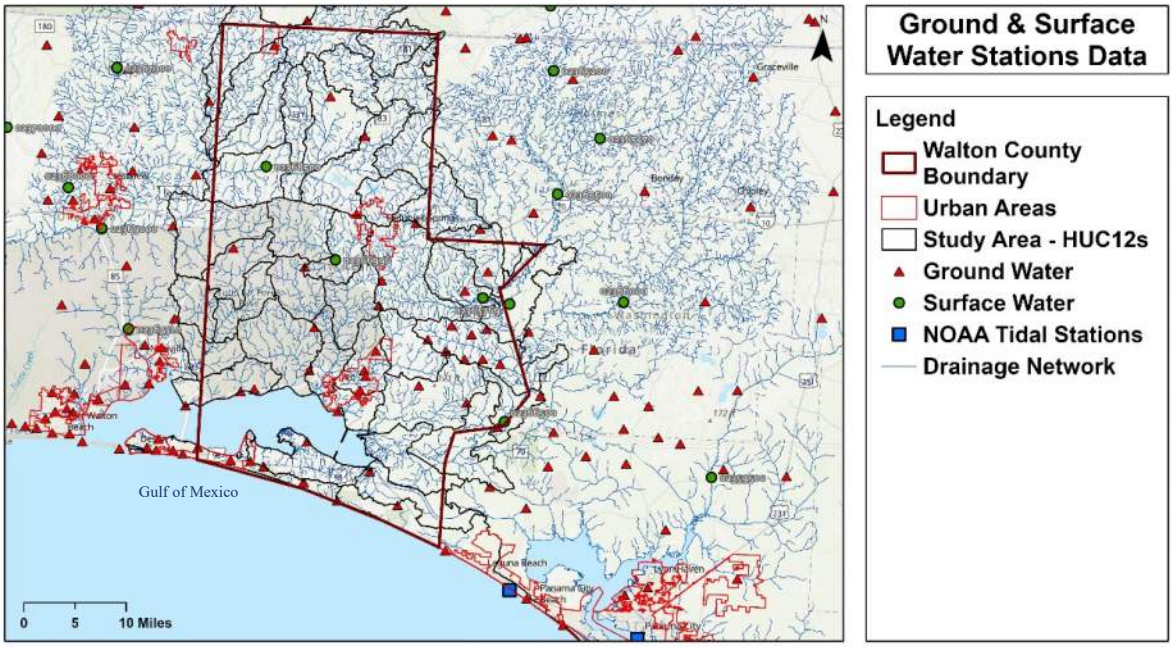

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401020501 has no major rivers and canals, but creeks include:

- Rocky Creek
- Wildcat Creek
- Bear Branch
- Green Head Branch

- Exline Creek
- Mount Sinai Branch

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366996. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401020501, which is USGS 02366996 Alaqua Creek Near Pleasant Ridge, FL

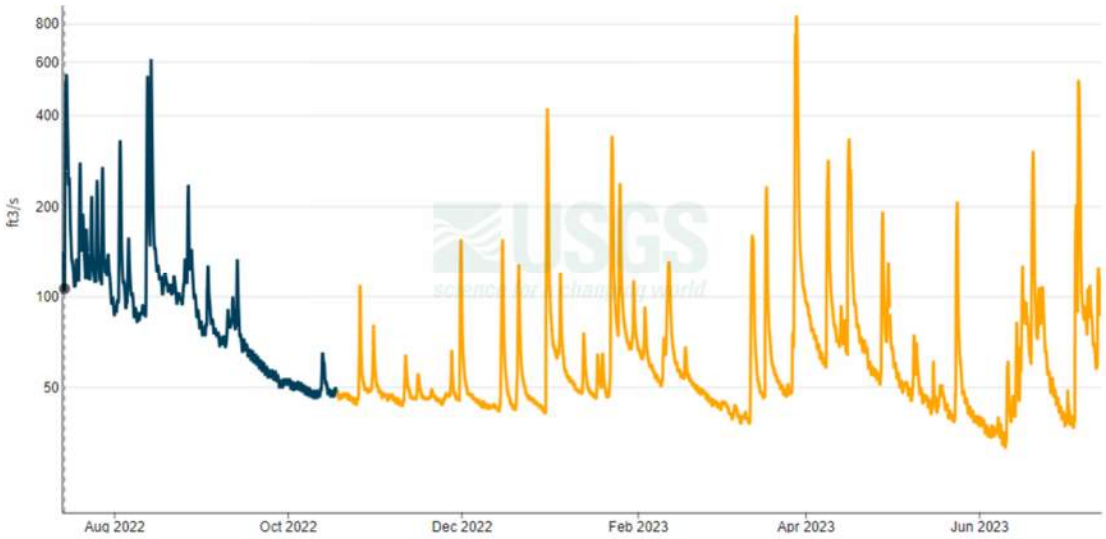

Figure 8. Average streamflow for Alaqua Creek Near Pleasant Ridge, FL (USGS 02366996 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366996/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401020501 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020501 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

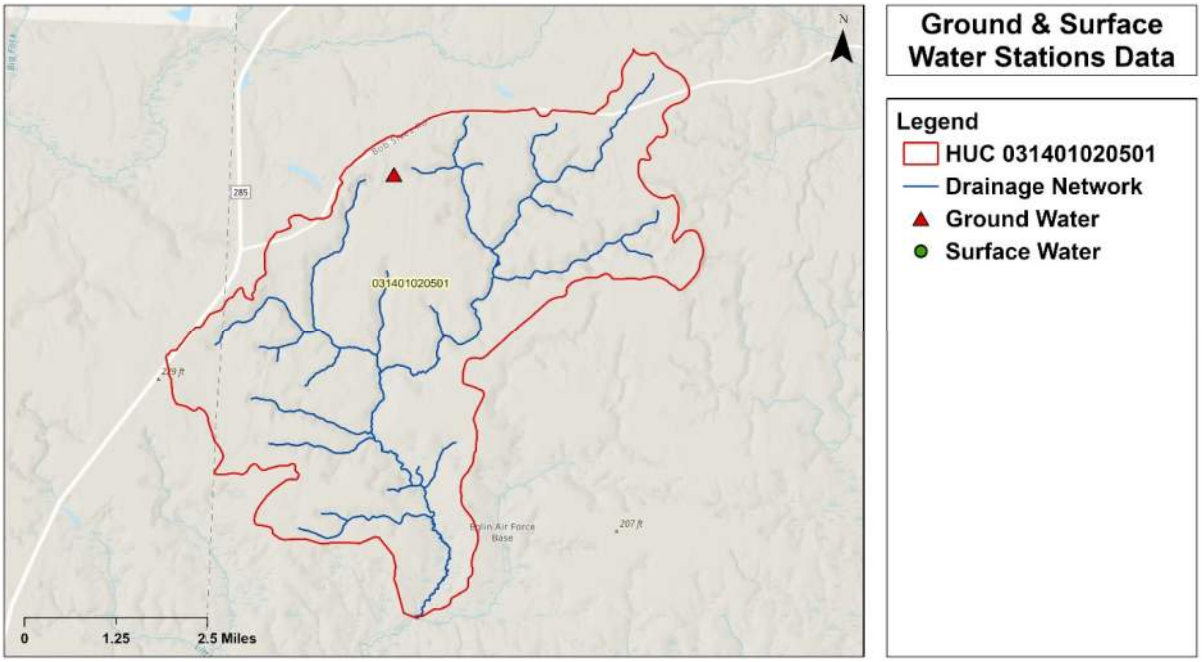

Figure 9. Ground and Surface Water Stations in the HUC 031401020501 sub-watershed, processed by FAU.

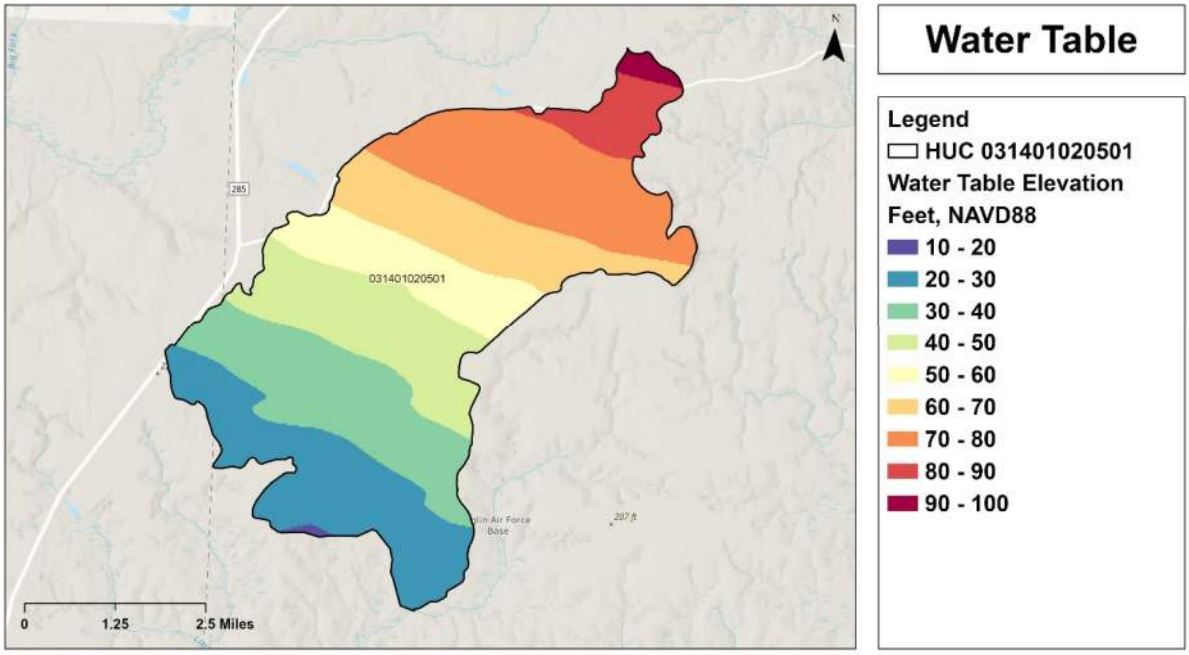

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020501 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

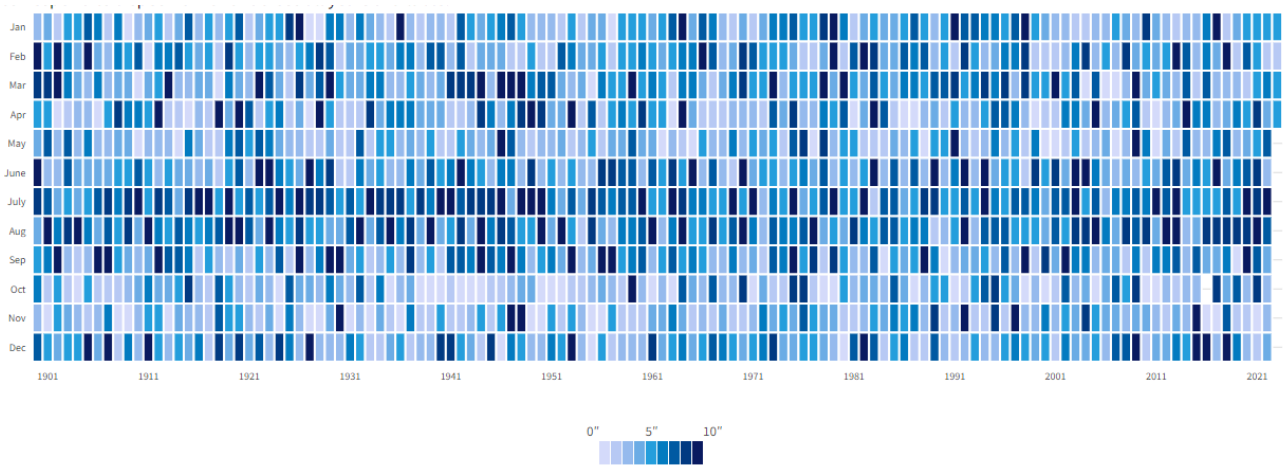

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

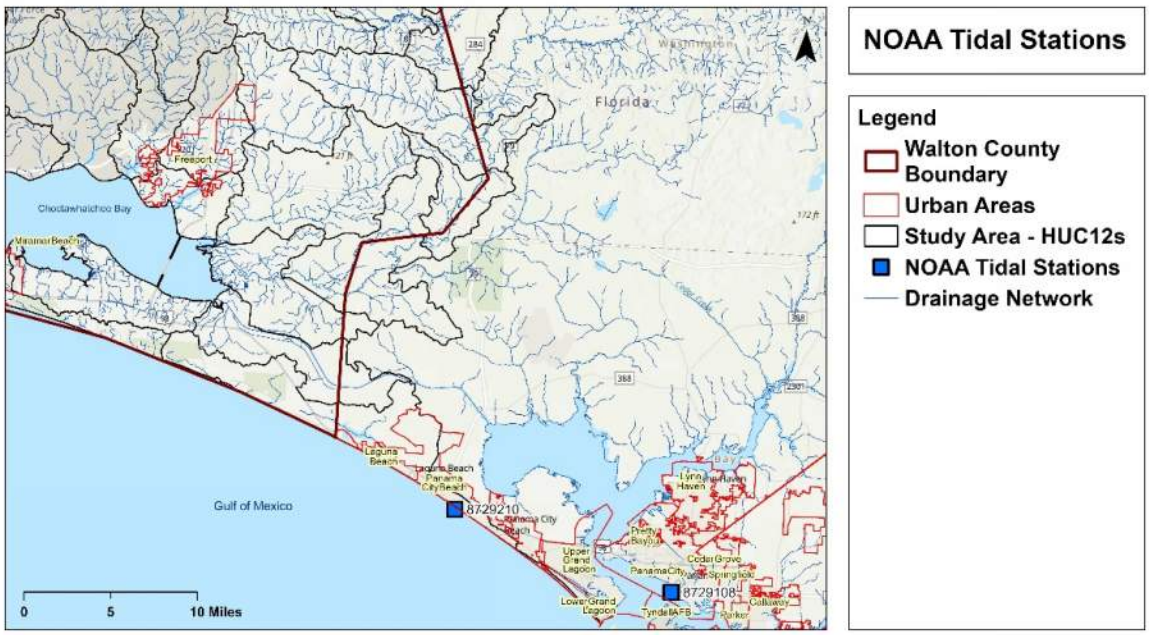

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

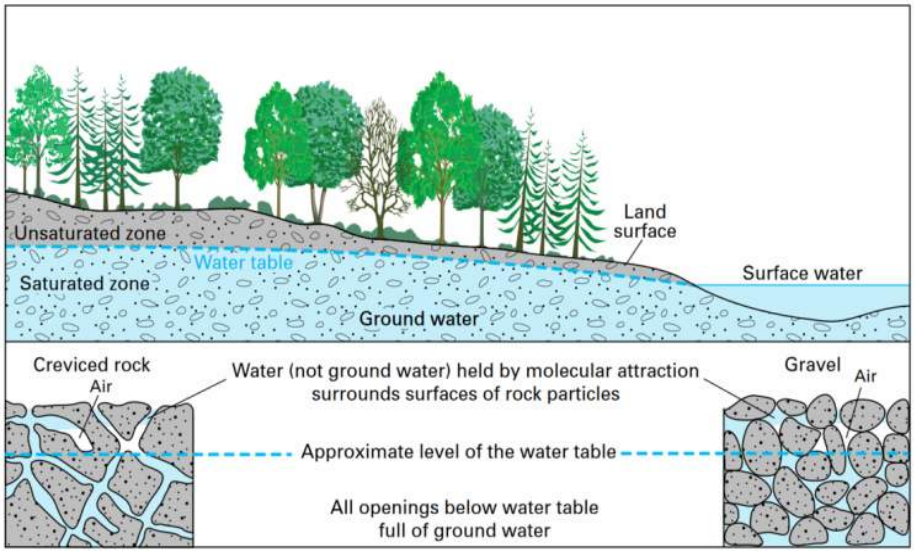

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

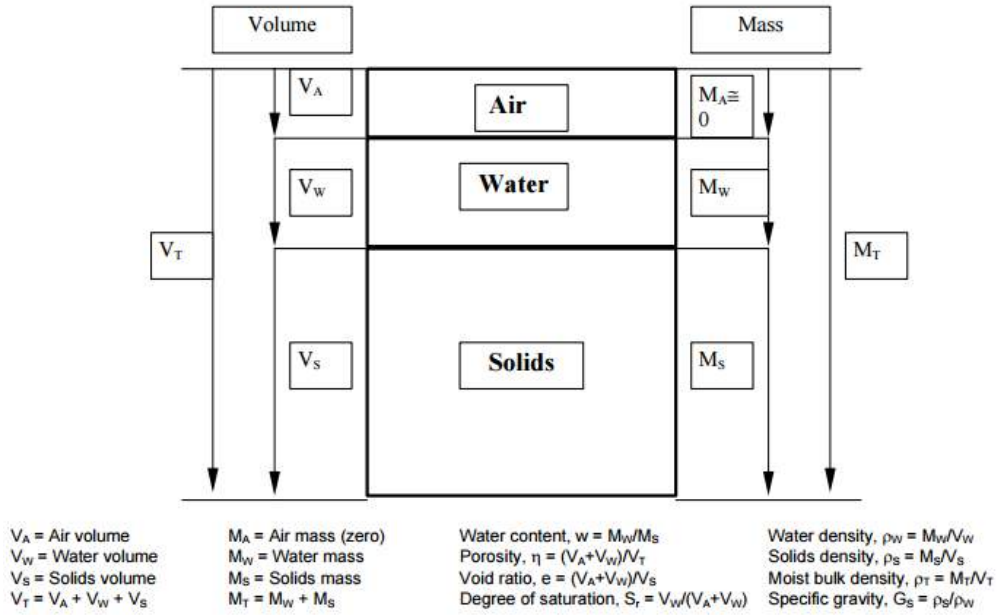

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

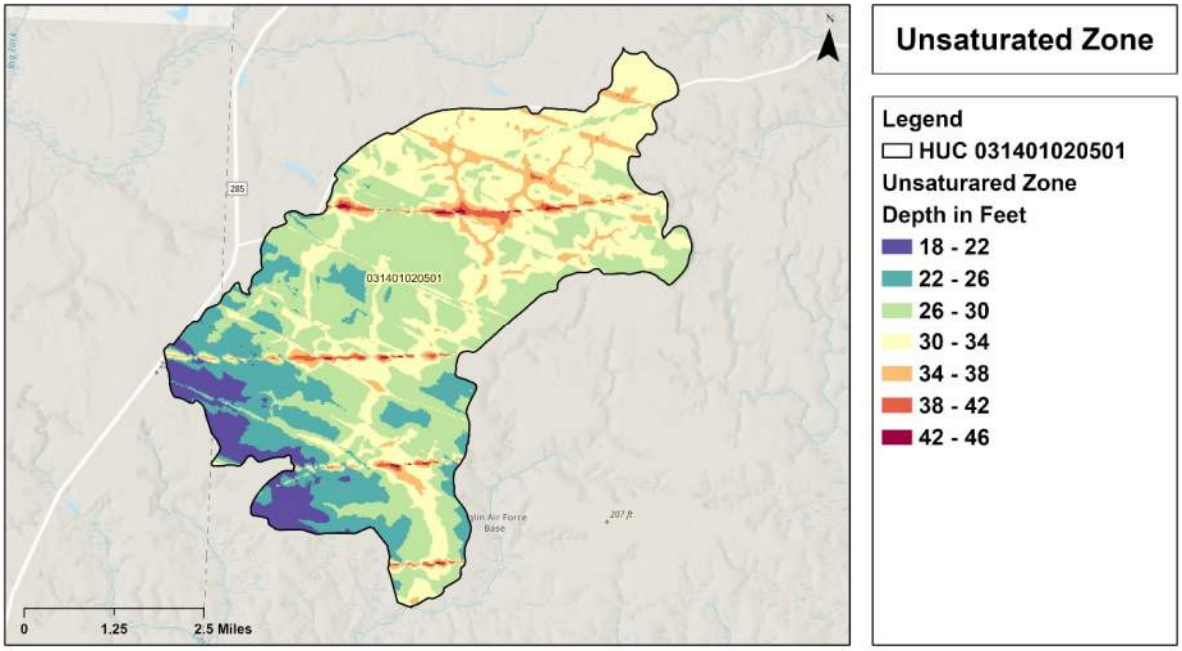

Figure 15. Unsaturated zone map for HUC 031401020501, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin demonstrates a moderately to limited soil storage capacity, falling within the range of 18 to 34 feet of remaining capacity.

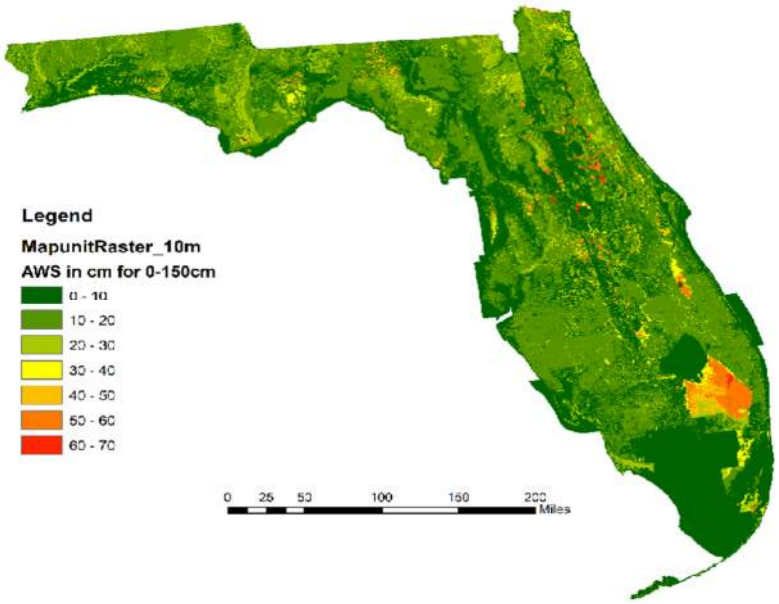

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

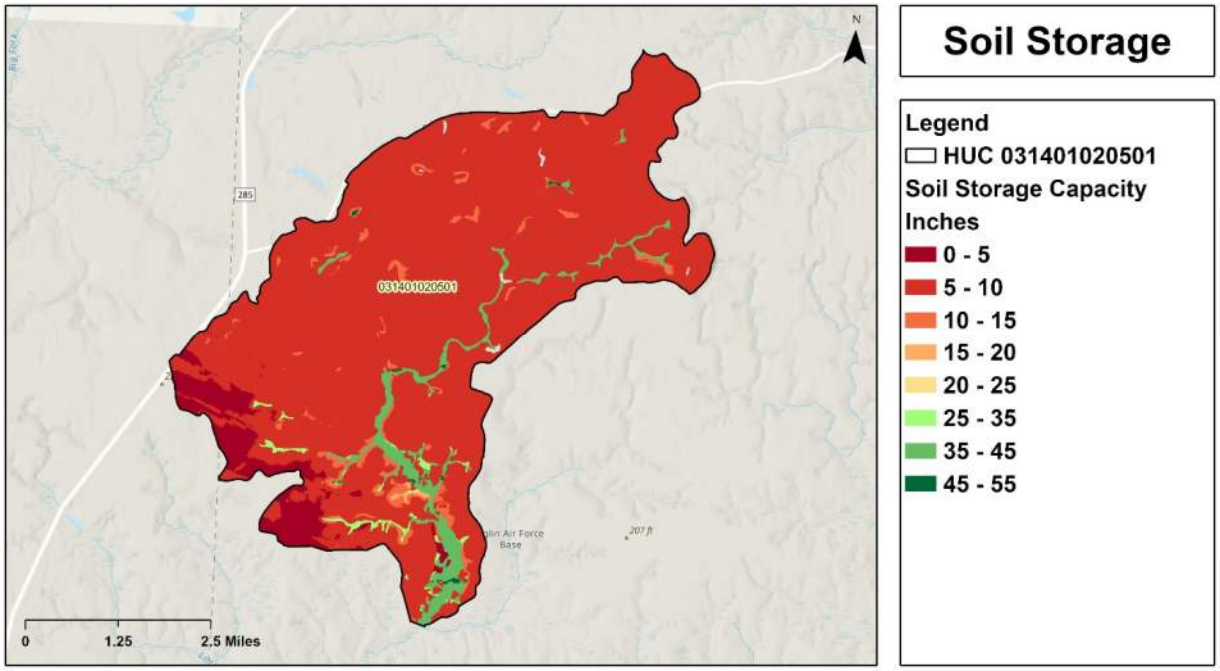

Figure 17. Water storage capacity of soil for the HUC 031401020501 (inches), processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

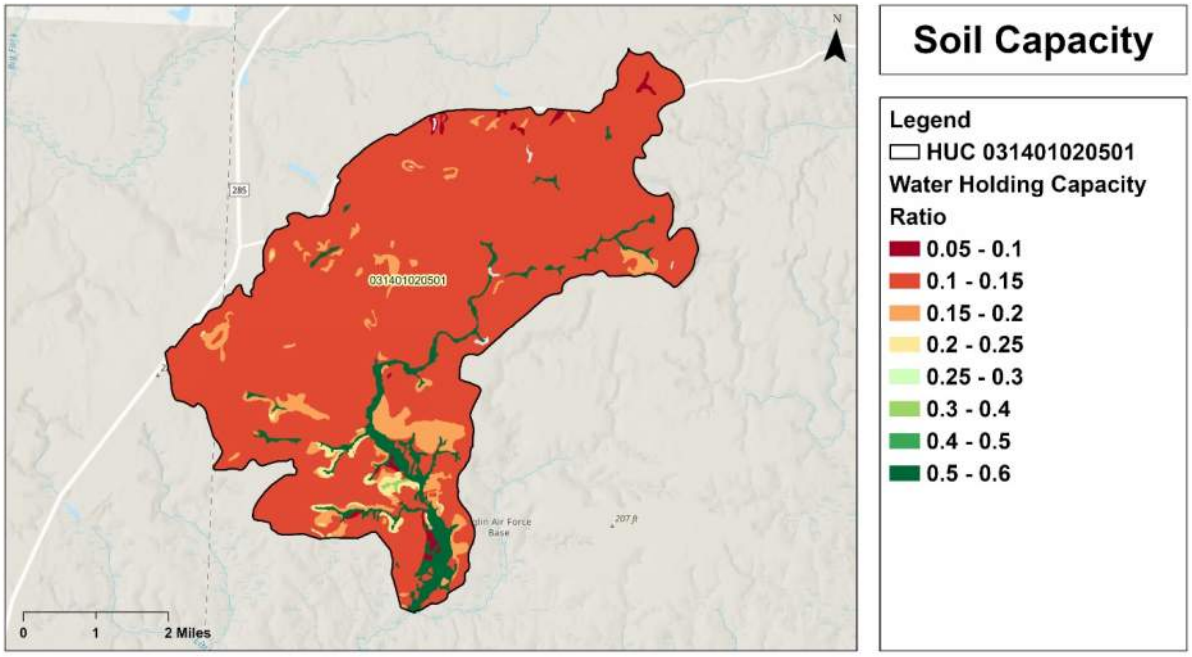

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020501, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

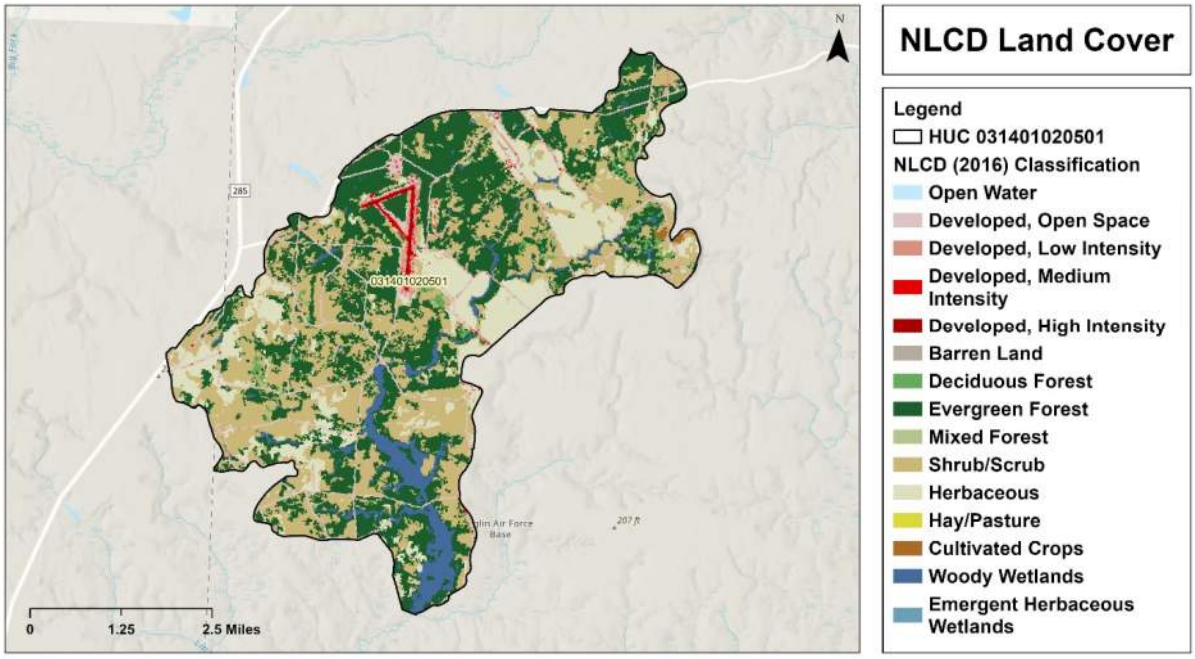

Figure 19. Land use in the HUC 031401020501 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

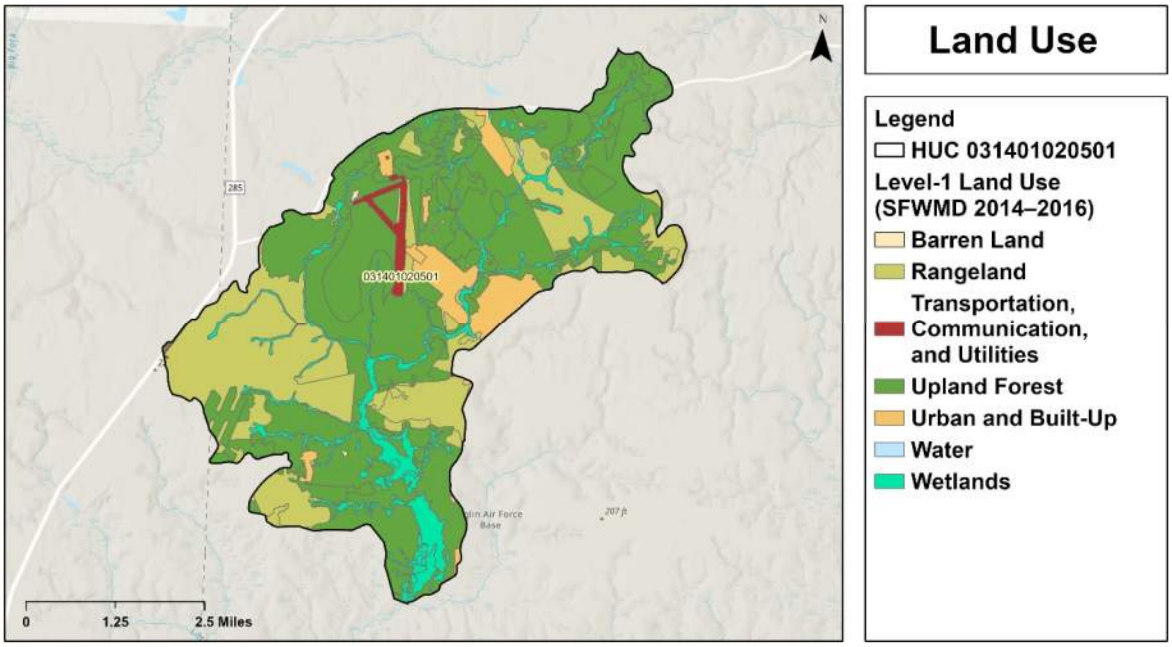

Figure 20. Land use in the HUC 031401020501 (from the (2023 Florida Geographic Data Library (FGDL)), processed by FAU.

In the HUC 031401020501 sub-watershed, the predominant land cover is upland forest, accounting for 57.79% of the area. Rangeland comes in second at 21.58%, followed by Transportation, Communication, and Utilities at 10.90%. Developed land constitutes a minor portion, with only 4.23% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401020501 subwatershed (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	0.00	0.00%
Barren Land	120.59	0.44%
Rangeland	5897.74	21.58%
Transportation, Communication, and Utilities	2979.47	10.90%
Upland Forest	15790.21	57.79%
Urban and Built-Up	1155.95	4.23%
Water	5.28	0.02%
Wetlands	1375.11	5.03%
Grand Total:	**27324.36**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

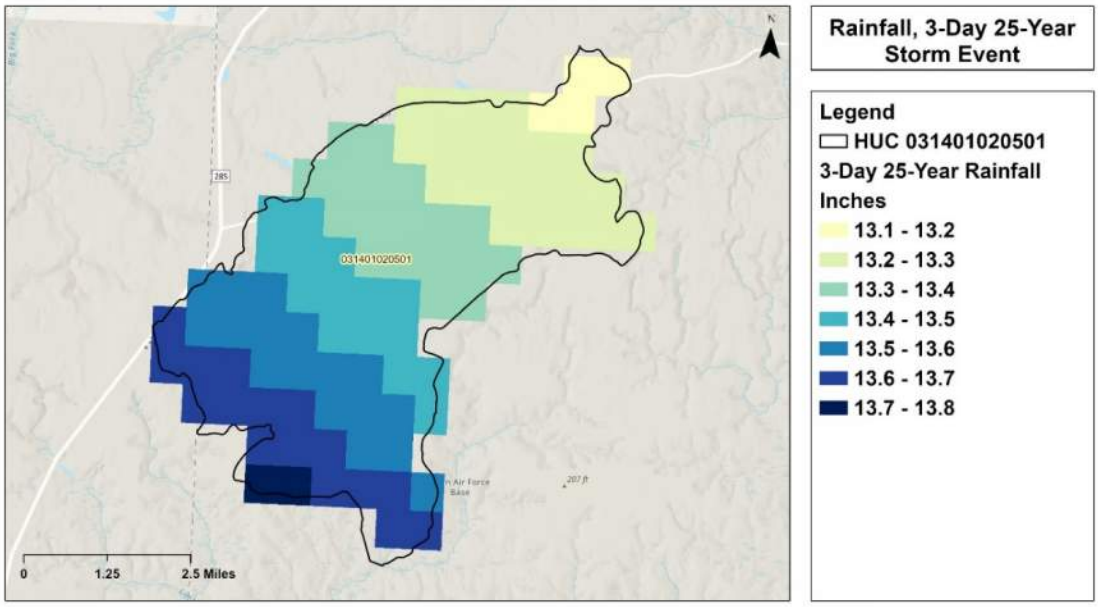

Figure 21. Rainfall distribution map across HUC 031401020501 sub-watershed, for 3-day 25-year storm event, processed by FAU.

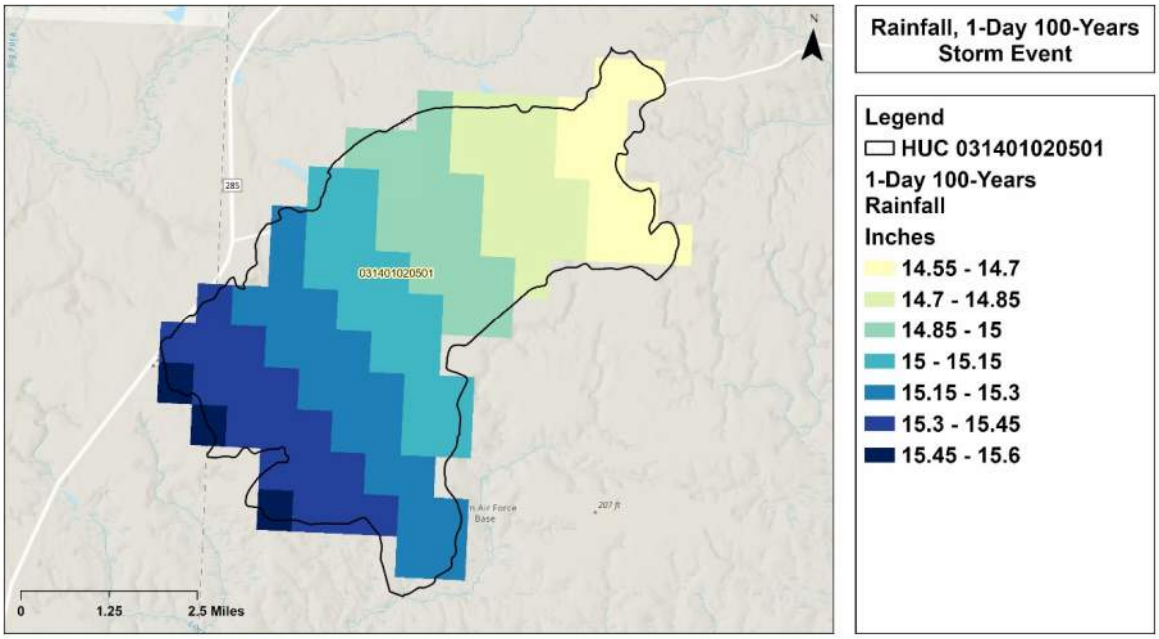

Figure 22. Rainfall distribution map across HUC 031401020501 sub-watershed, for 1-day 100-year storm event, processed by FAU.

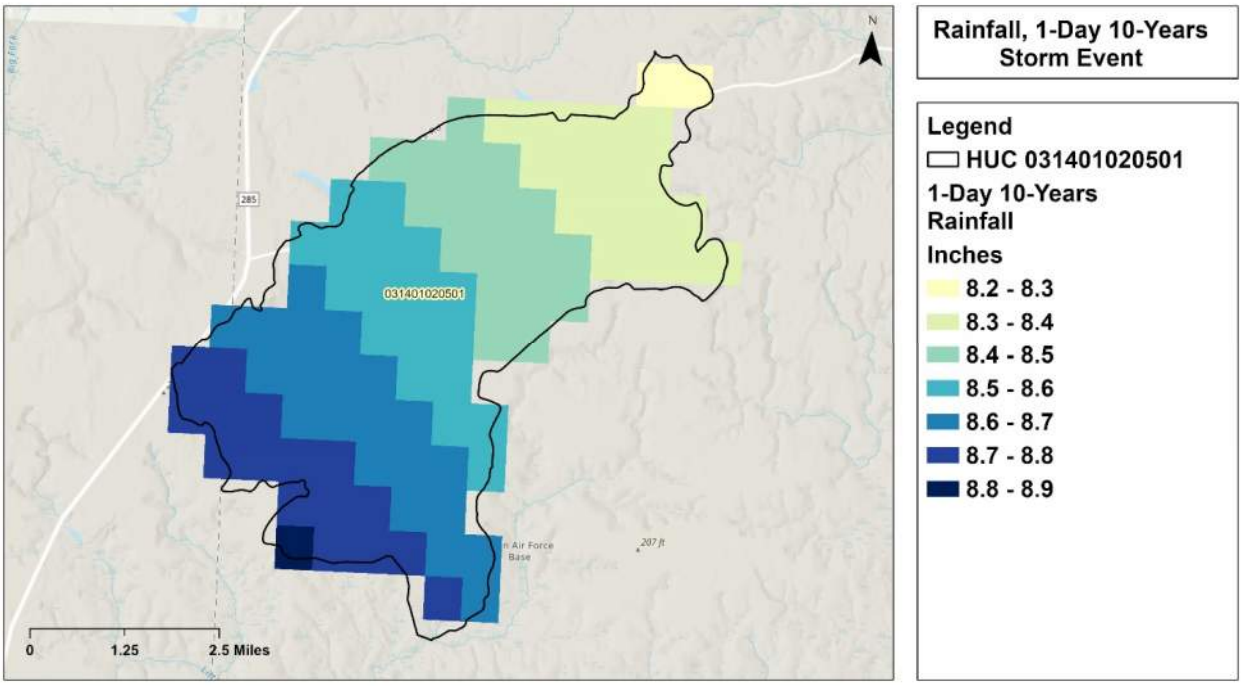

Figure 23. Rainfall distribution map across HUC 031401020501 sub-watershed, for 1-day 10-year storm event, processed by FAU.

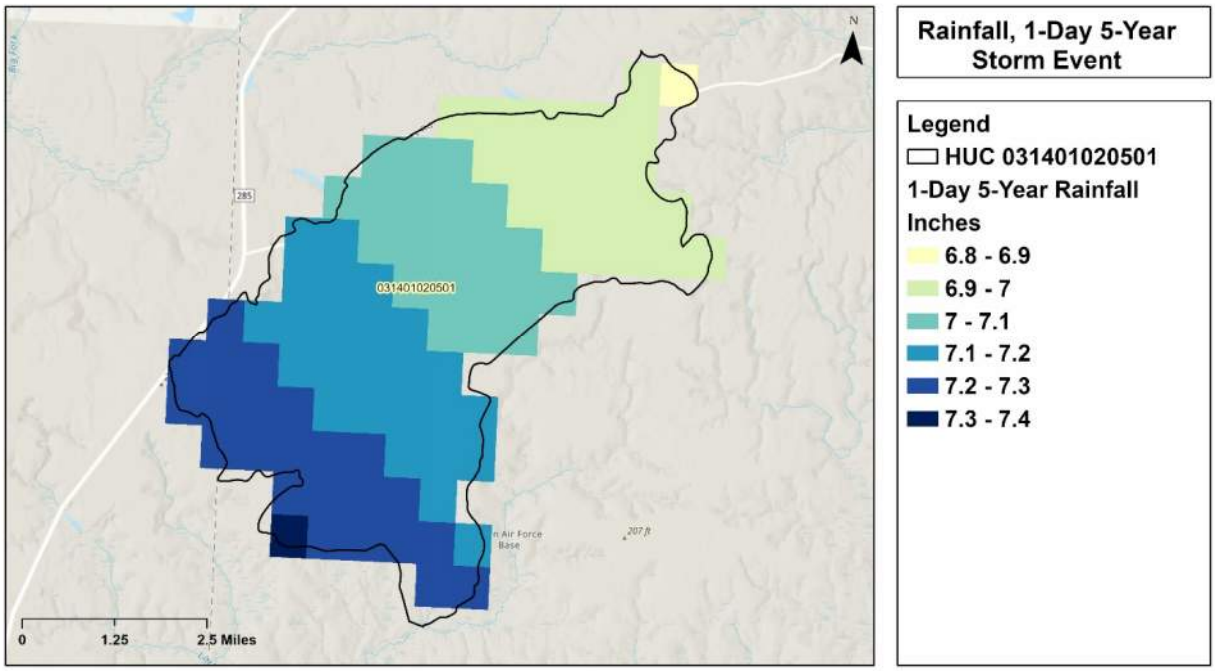

Figure 24. Rainfall distribution map across HUC 031401020501 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer

was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

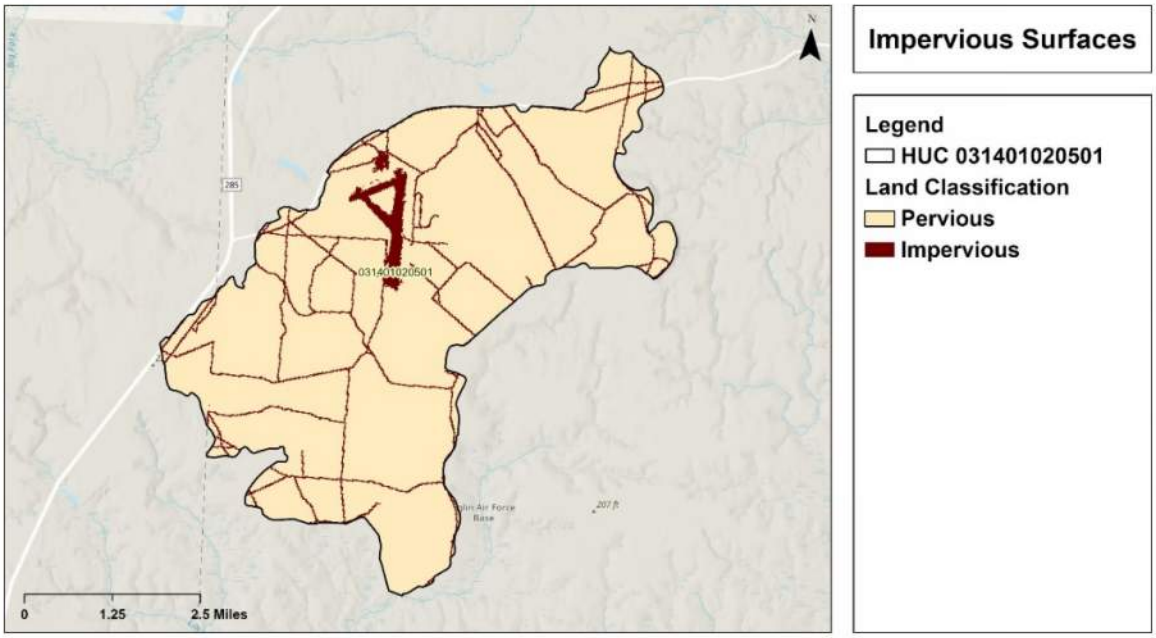

Figure 25. Impervious area map for the HUC 031401020501 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

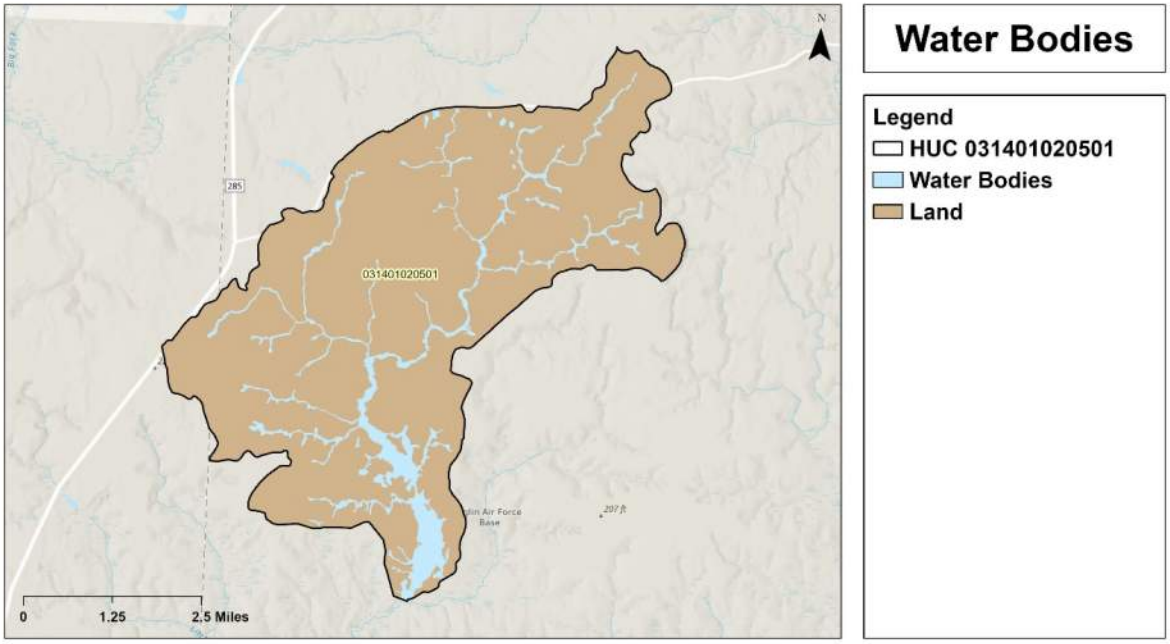

Figure 26. Water bodies map for the HUC 031401020501 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

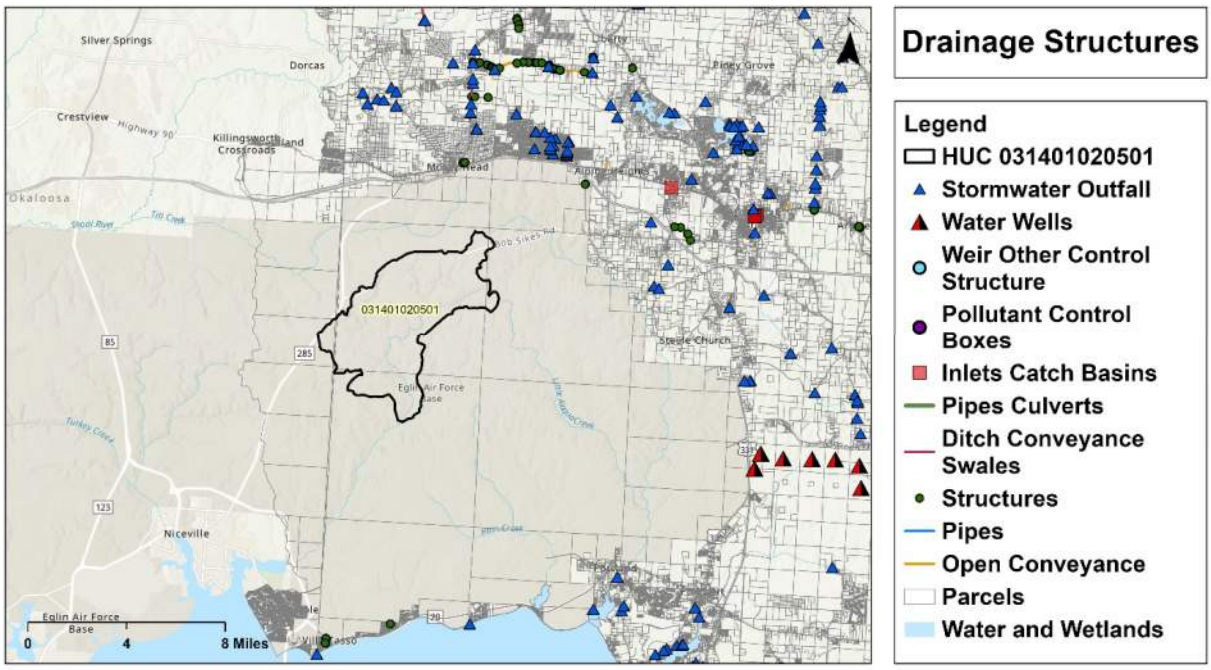

Figure 27. Stormwater Infrastructure for the HUC 031401020501. Processed by FAU.

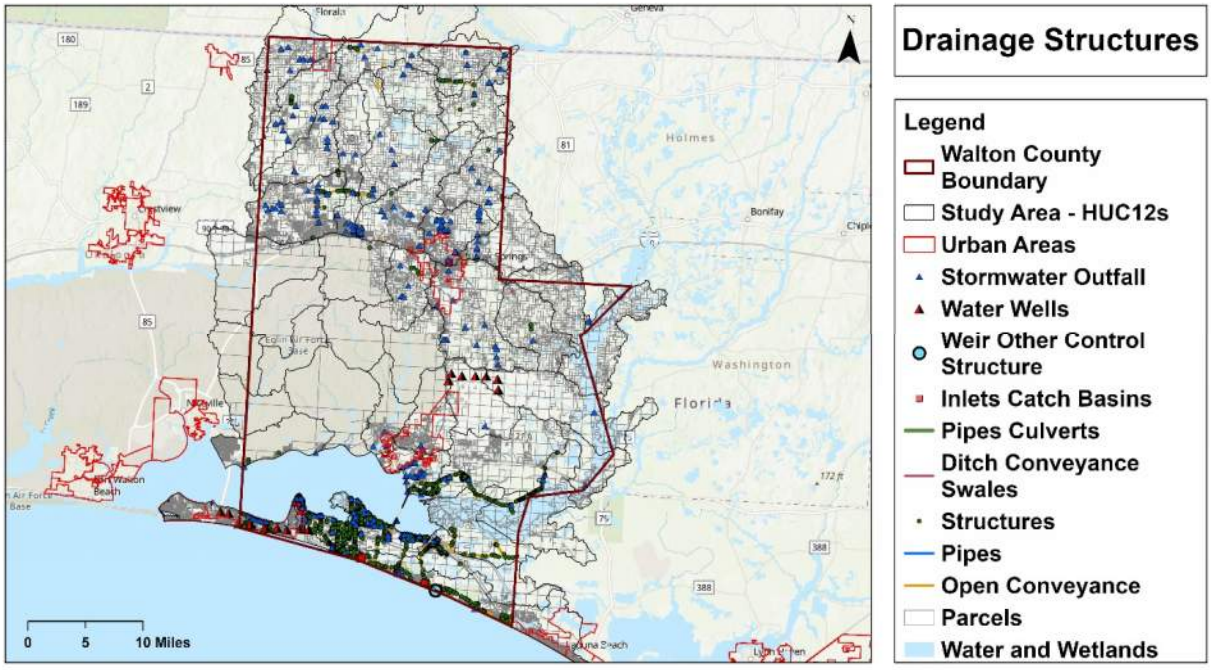

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020501 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the

coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

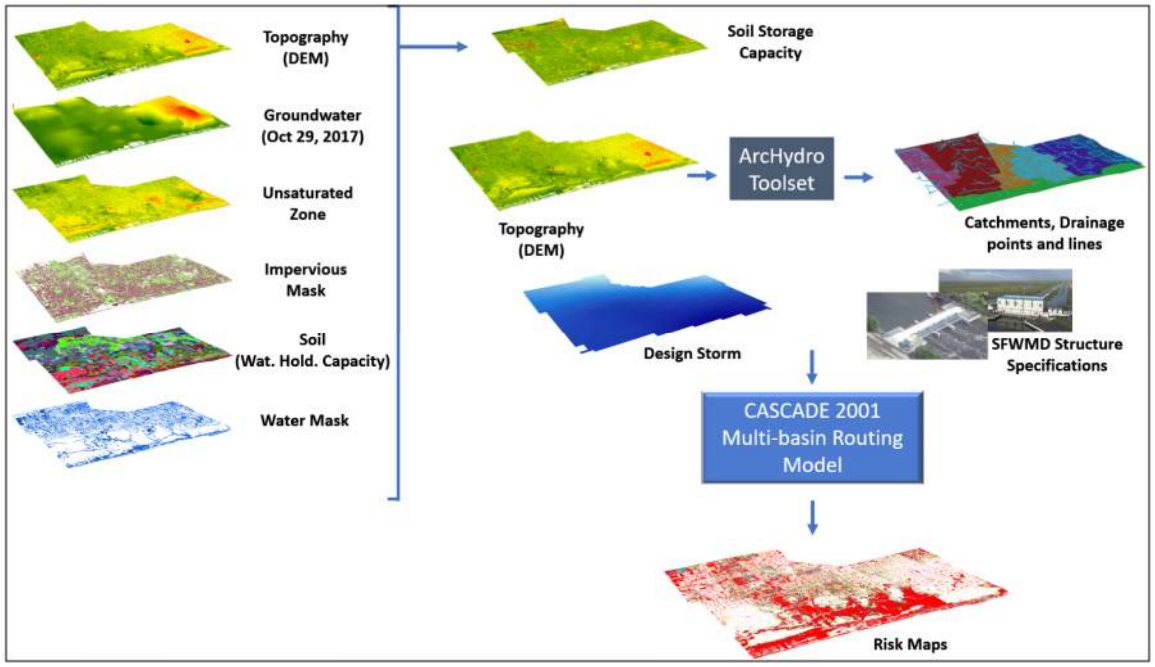

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

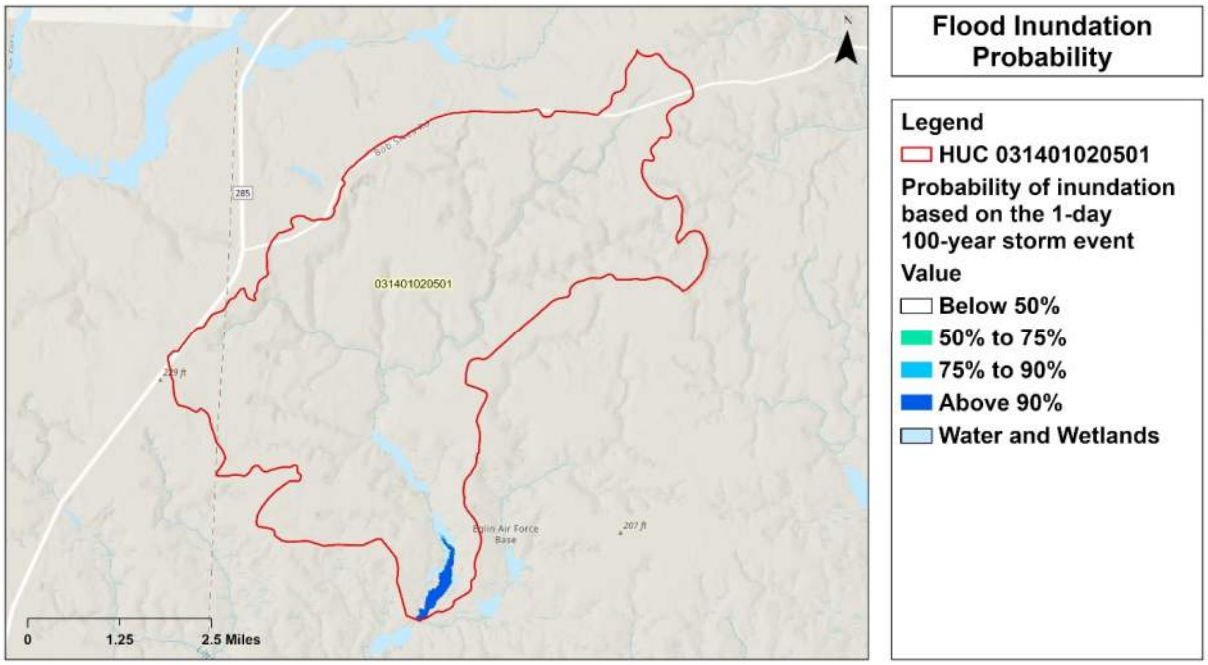

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020501, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate

the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.6% of the HUC total area or 0.15 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.6% of the HUC's total area, or 0.15 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.5% of the HUC's total area, or 0.11 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.4% of the HUC's total area, or 0.09 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401020501 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	25.02	0.15	99.4%	0.6%
1-day 100-year	25.02	0.15	99.4%	0.6%
1-day 10-year	25.05	0.11	99.5%	0.5%
1-day 5-year	25.07	0.09	99.6%	0.4%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4

60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401020501 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

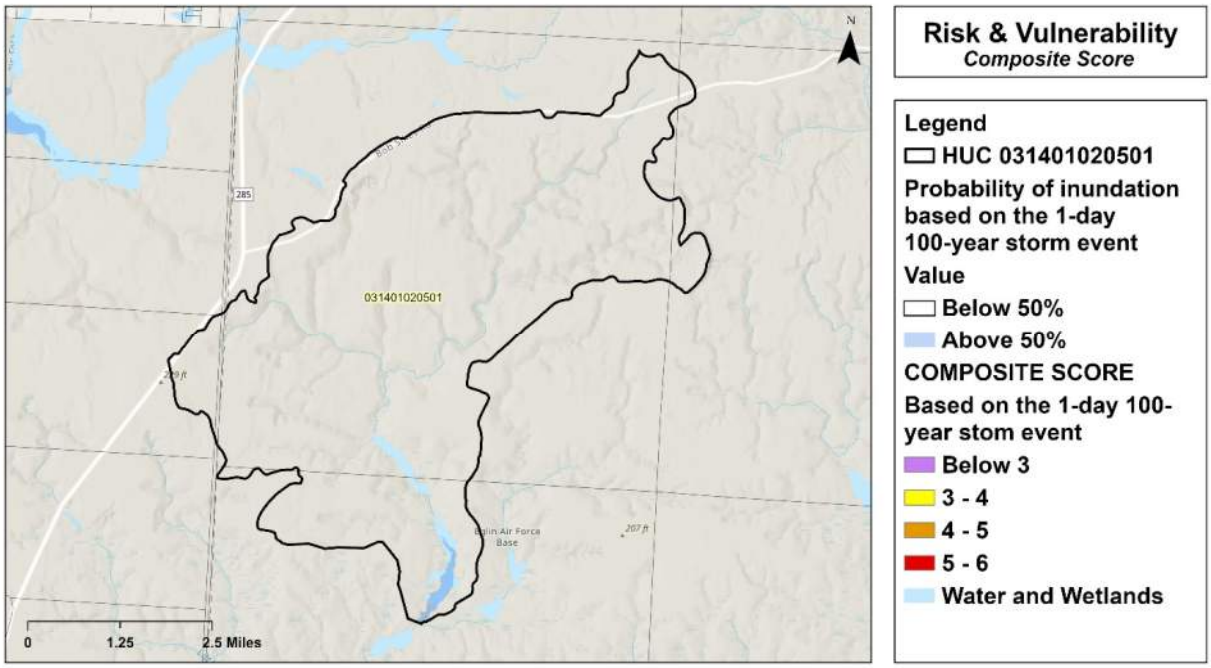

Figure 38. HUC 031401020501 sub-watershed Composite Score Risk map, with calculation based on 1-day 100-year storm event. Processed by FAU.

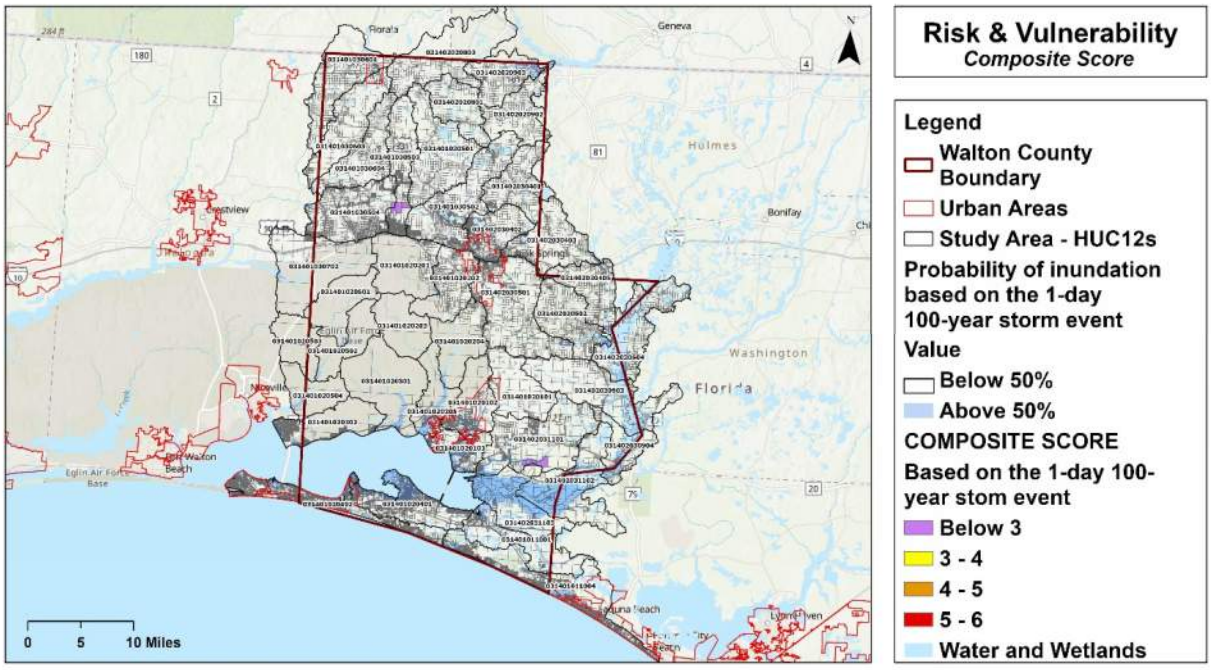

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020501. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020501. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020501	16106.26
All of the 1-day 100-year storm event inundation	**93.40**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	57.92
B. Federal Land in 1-day 100-year inundation > 10 acres	35.48
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	0.00
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	0.00

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

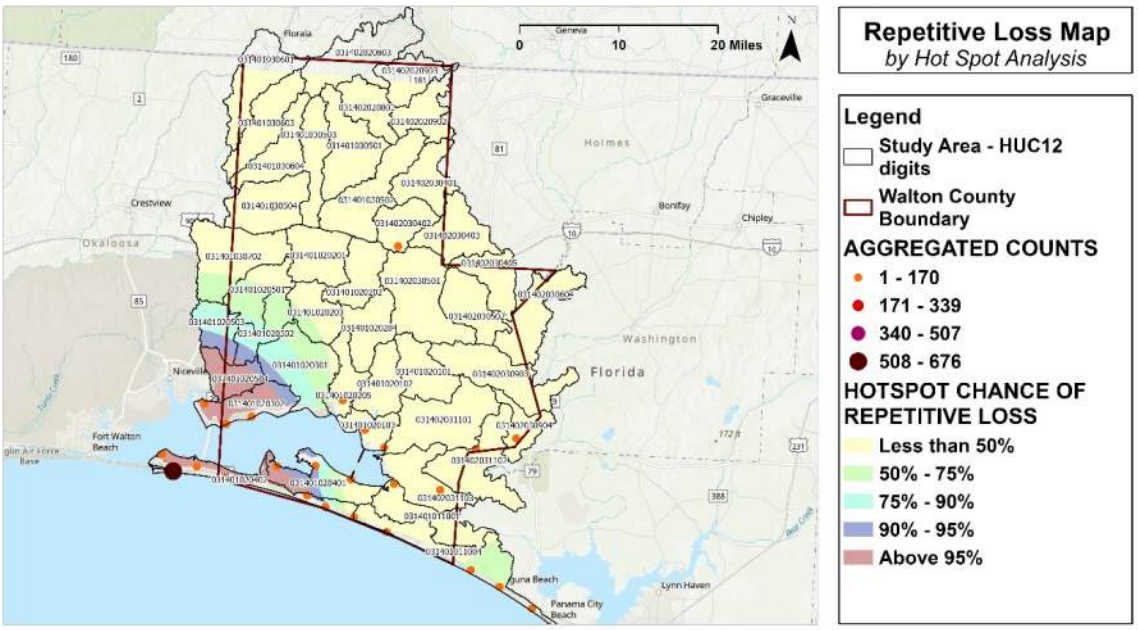

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5. Priority Projects

The entire HUC area is undeveloped and non-coastal. As a result, there are no critical facilities or other land uses that require priority intervention. The minor flooding and null composite score indicate that the HUC is not significantly affected by flooding, and there are no pressing priorities for interventions to address inundation impacts.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020502) is highlighted among all the HUCs to help identifying its location. (Figure 3).

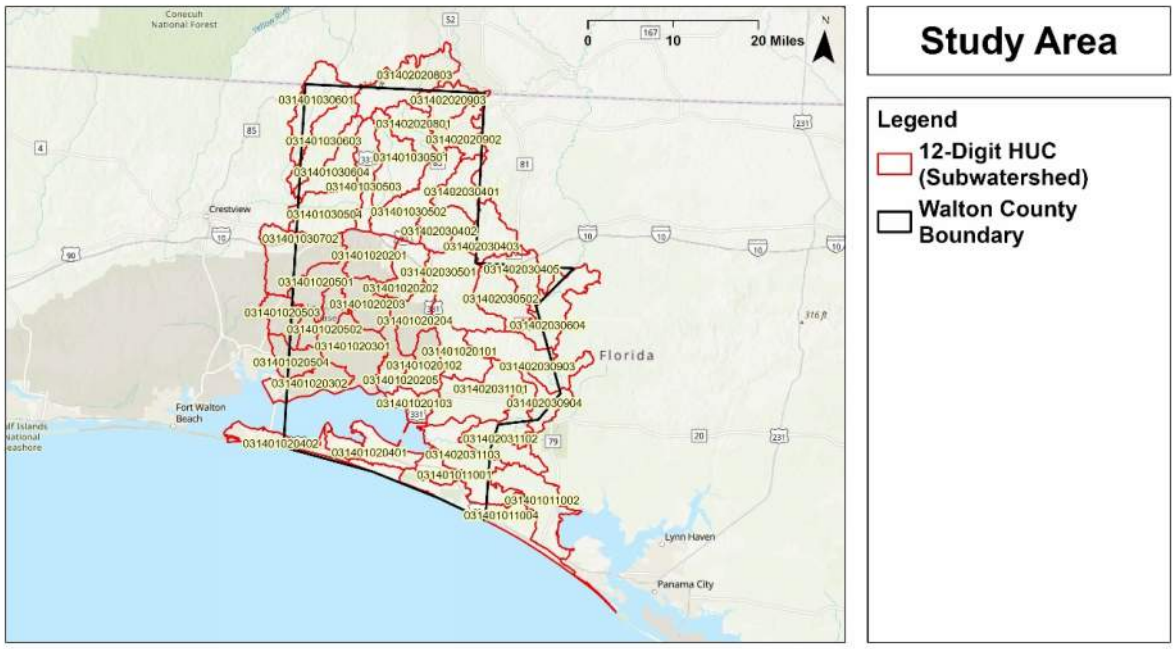

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

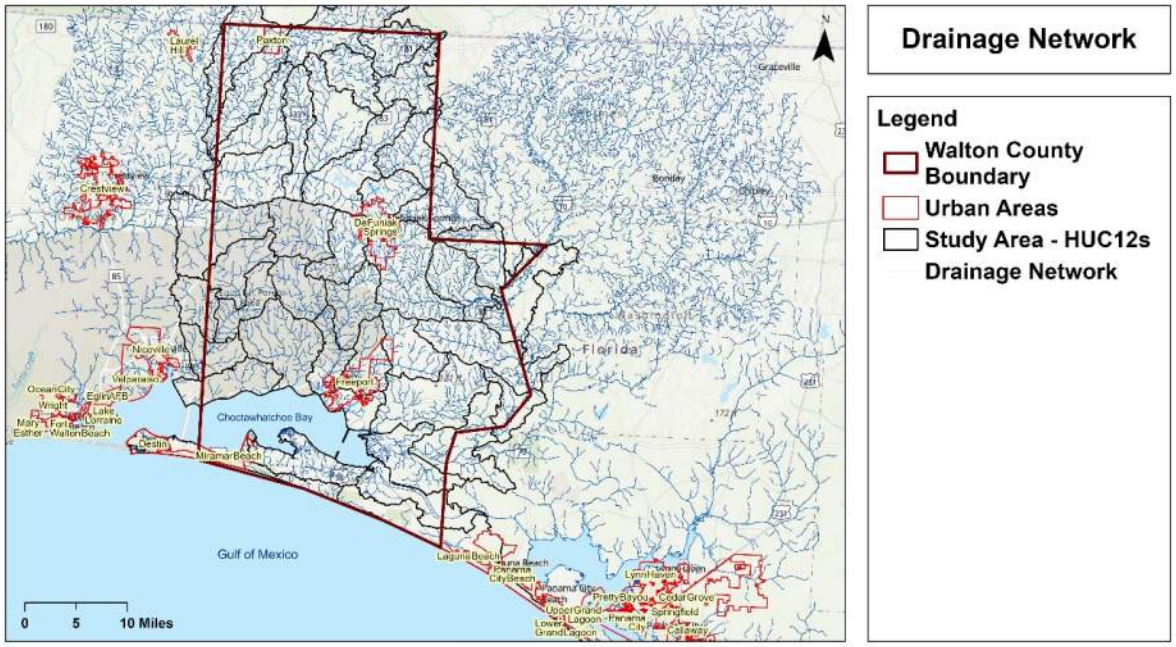

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

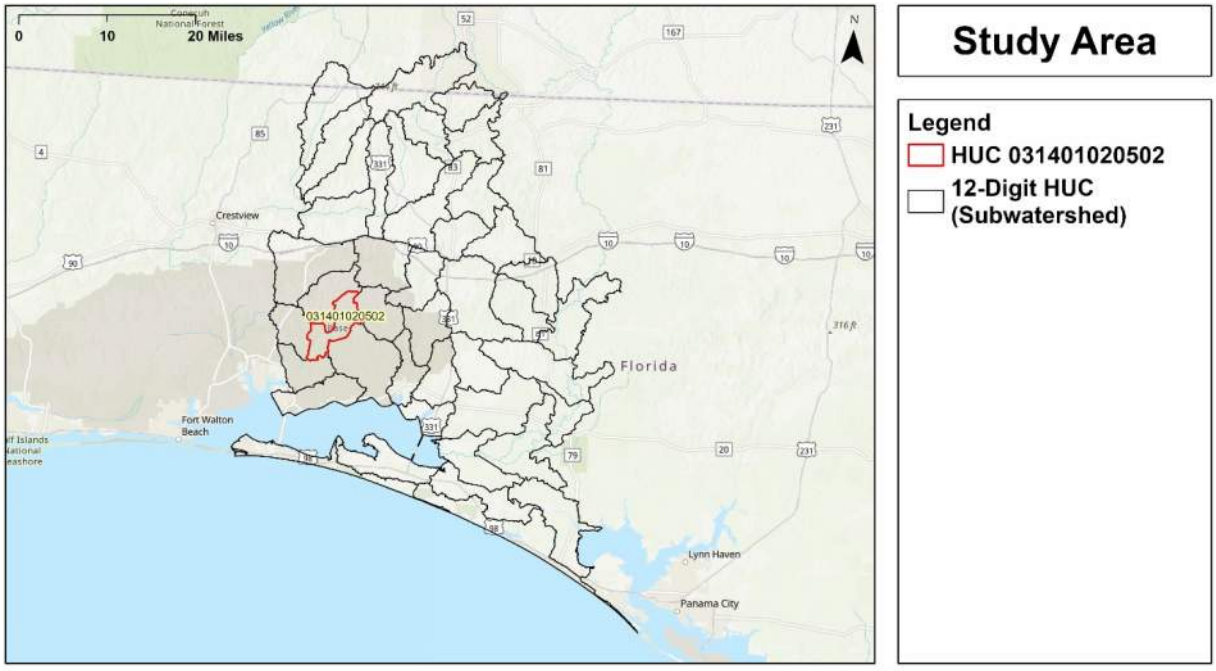

Figure 3. HUC 031401020502 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development, tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%

Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.

- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

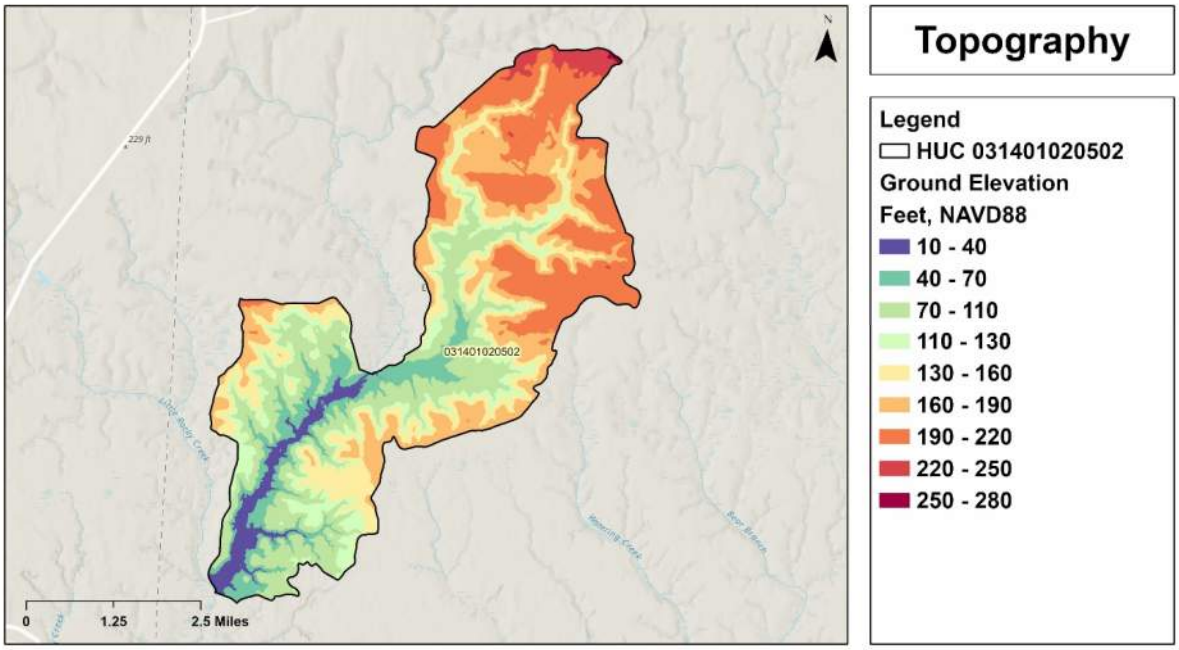

Figure 4. Topographic map of the HUC 031401020502 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020502 sub-watershed is shown in **Error! Reference source not found.**.

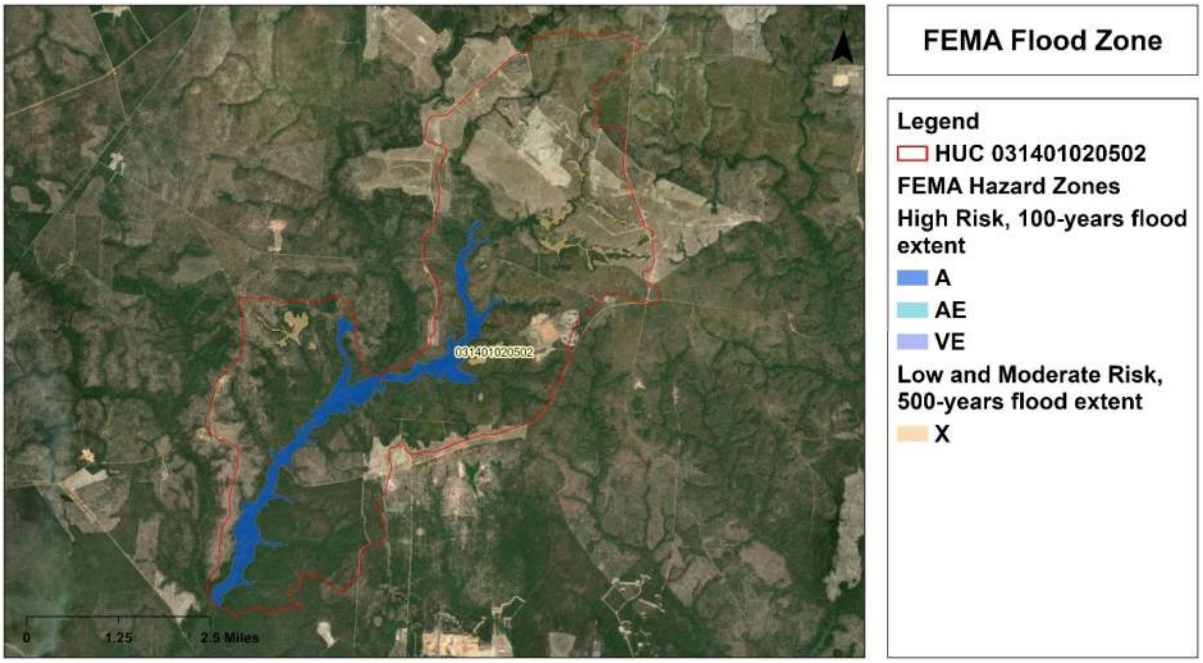

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020502 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401020502 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing.

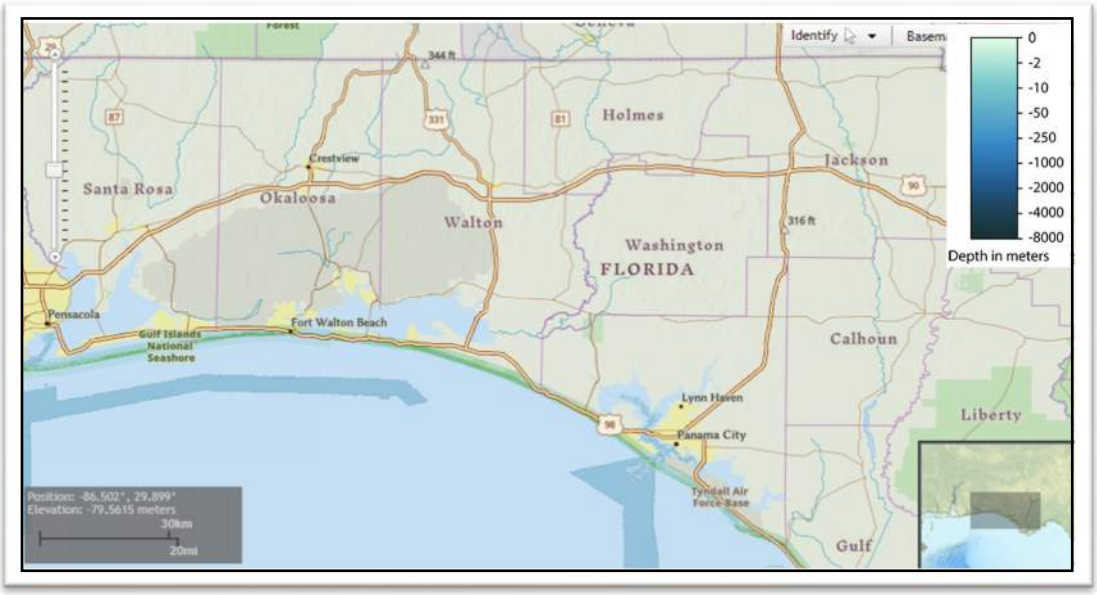

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

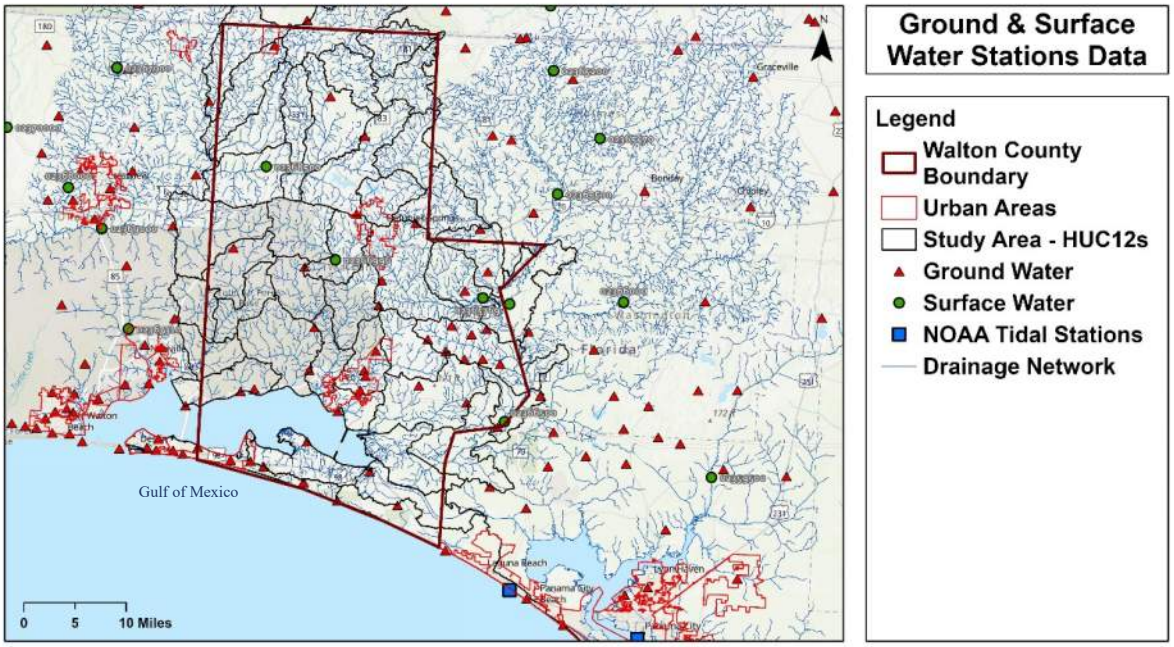

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401020502 has no major rivers and canals, but creeks and branches include:

- Cedar Head Branch
- Rocky Creek
- Fox Branch
- Old Peg Branch

- Schoolhouse Branch
- East Rocky Creek
- Open Branch

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366996. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401020502, which is USGS 02366996 Alaqua Creek Near Pleasant Ridge, FL.

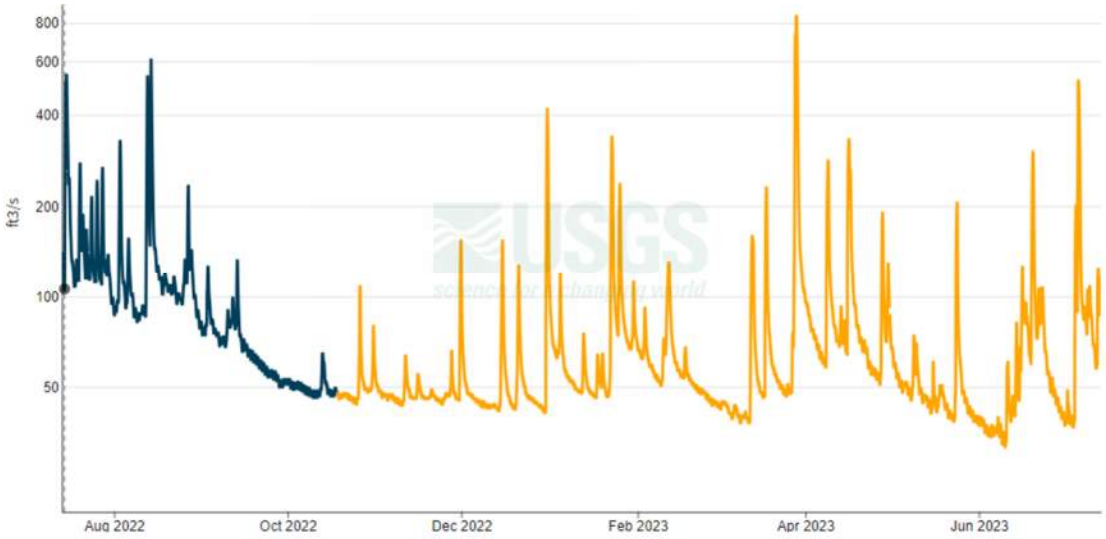

Figure 8. Average streamflow for Alaqua Creek Near Pleasant Ridge, FL (USGS 02366996 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366996/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401020502 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020502 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

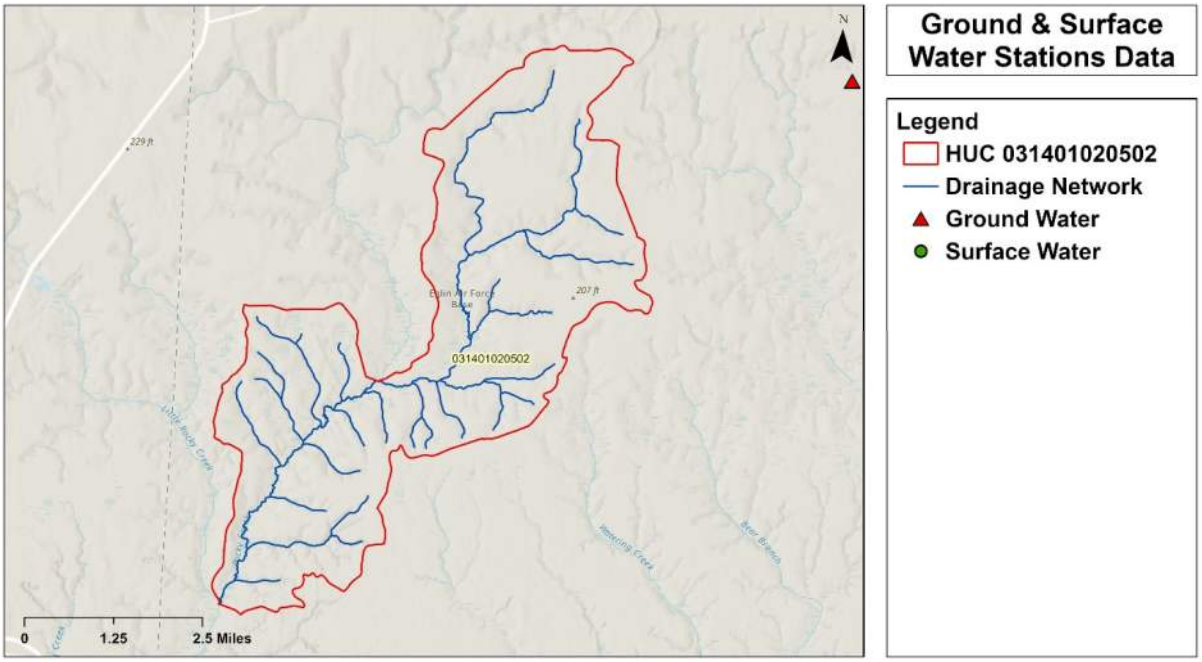

Figure 9. Ground and Surface Water Stations in the HUC 031401020502 sub-watershed, processed by FAU.

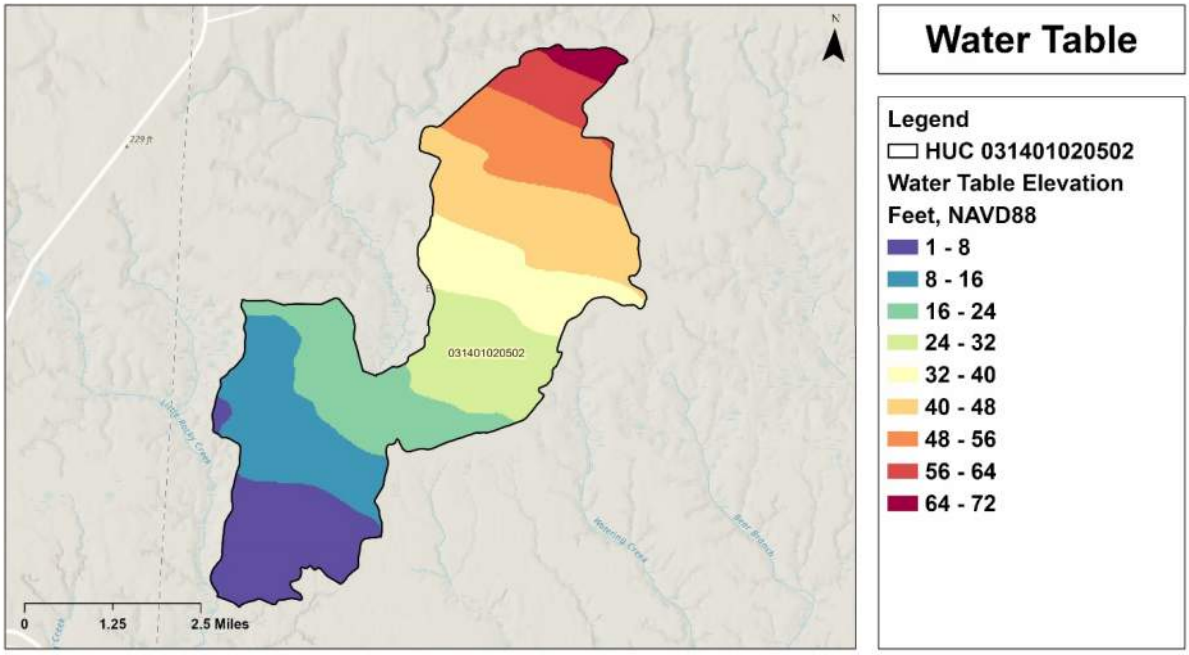

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020502 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

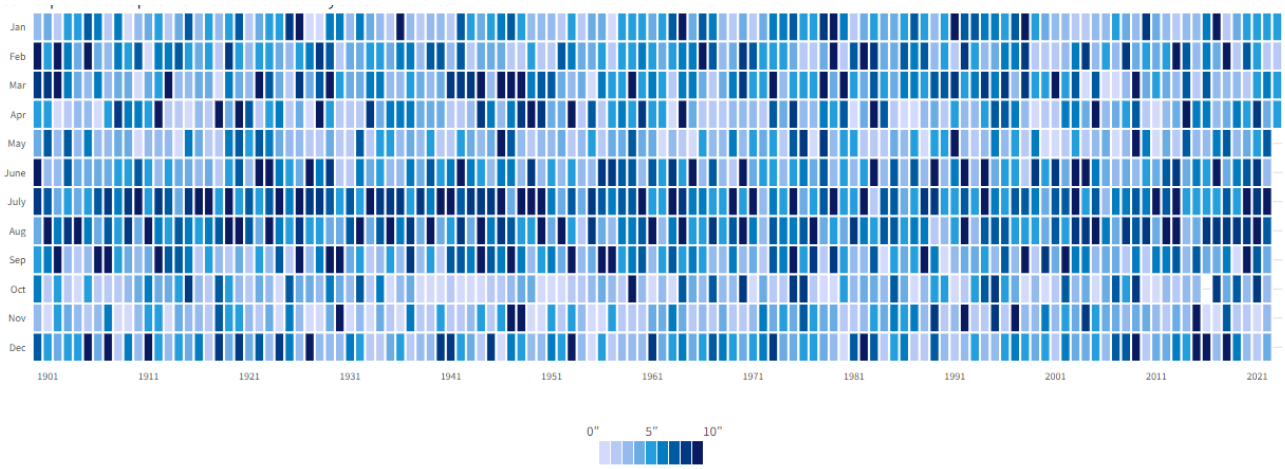

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

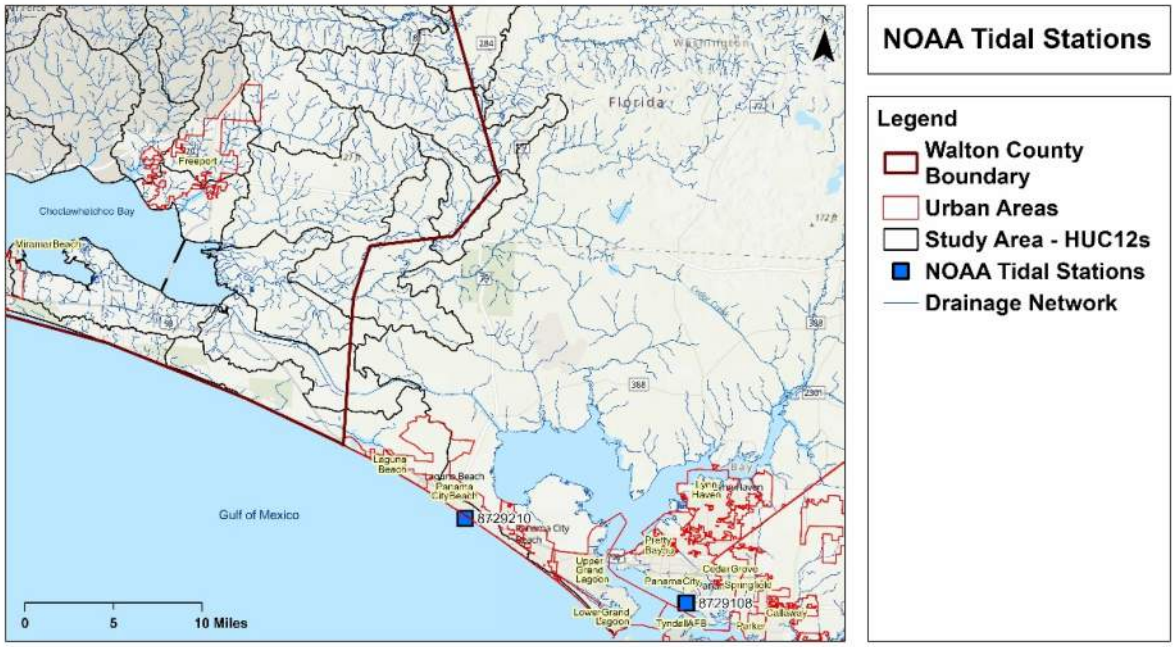

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

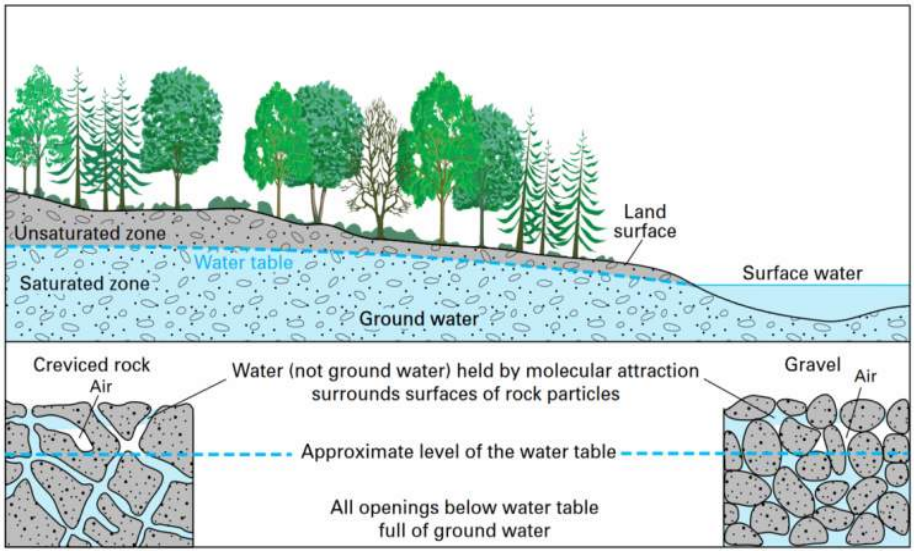

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

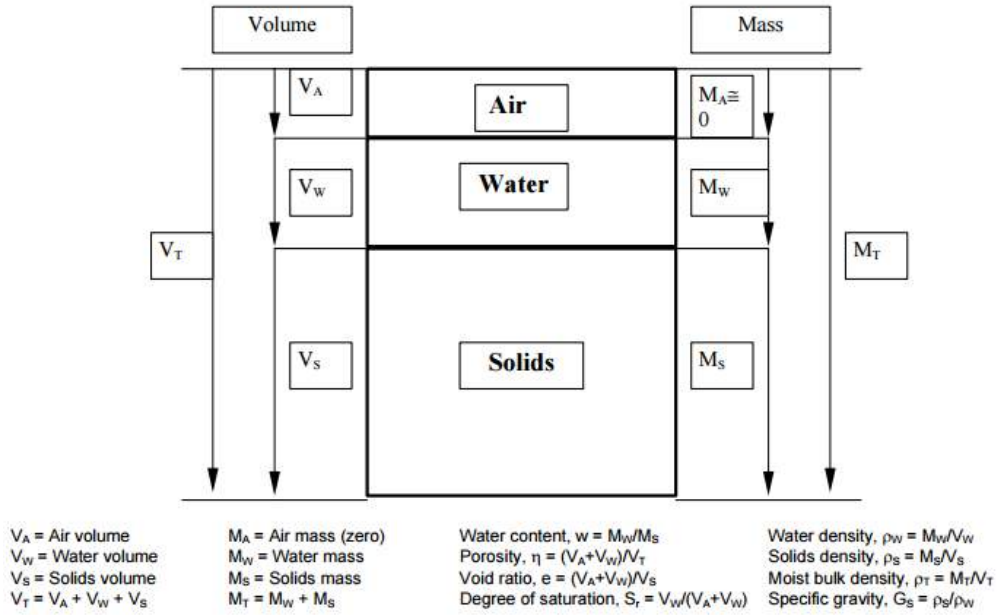

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

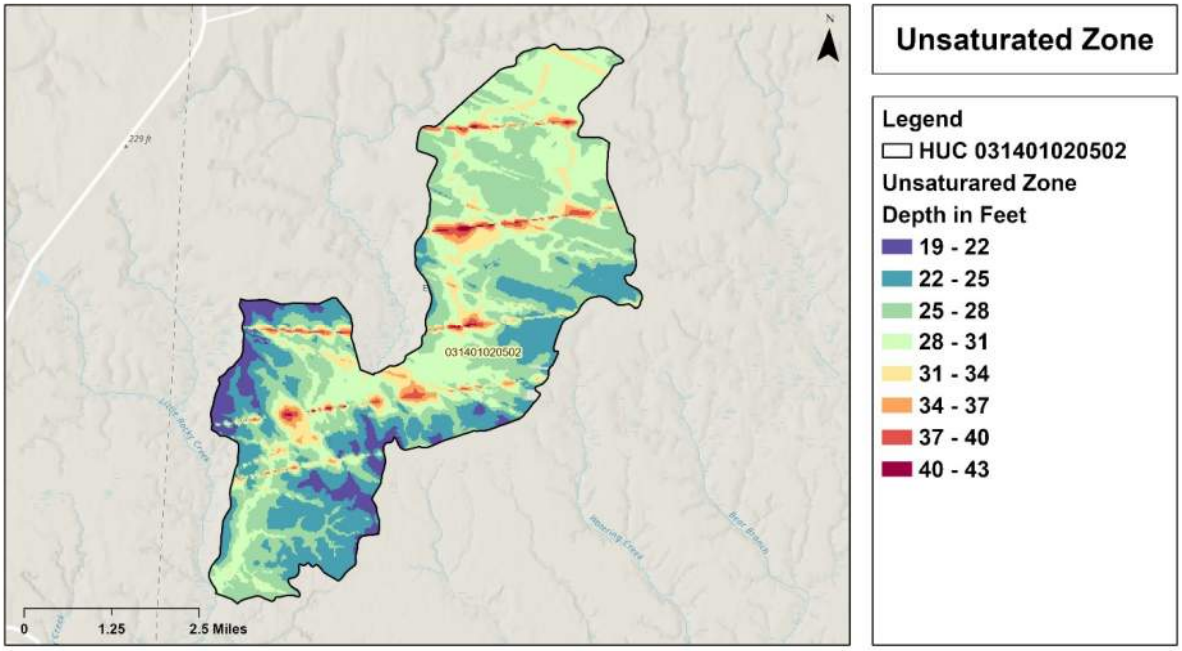

Figure 15. Unsaturated zone map for HUC 031401020502, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin demonstrates a moderately favorable soil storage capacity, falling within the range of 22 to 34 feet of remaining capacity.

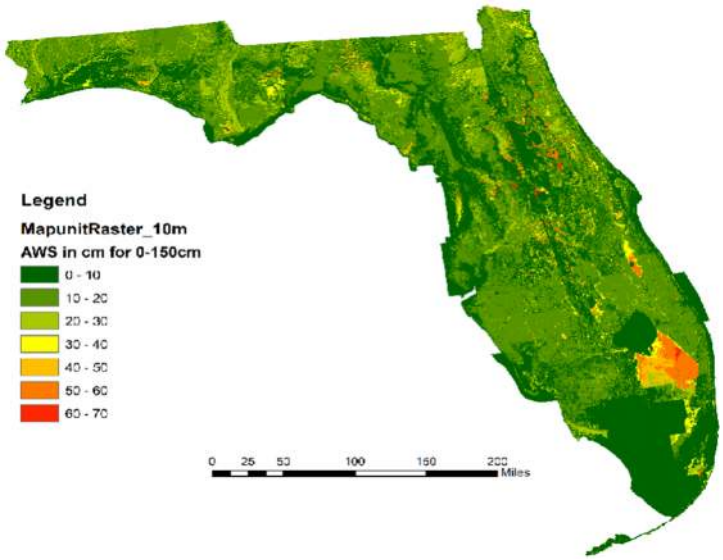

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

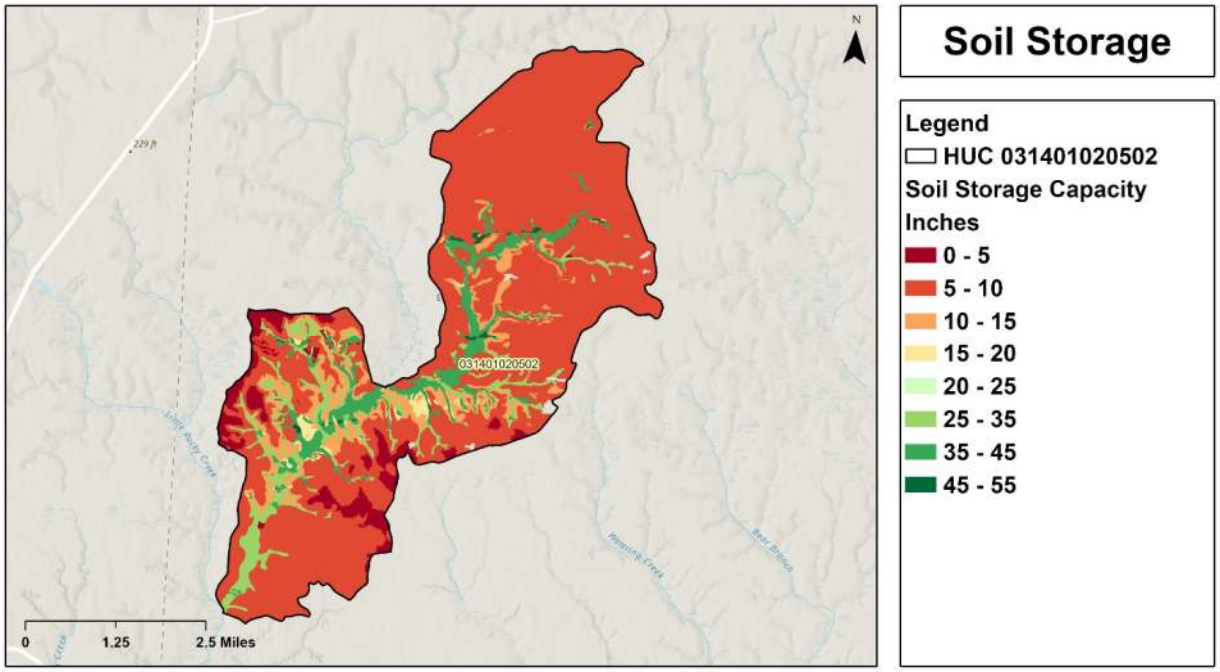

Figure 17. Water storage capacity of soil for the HUC 031401020502, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

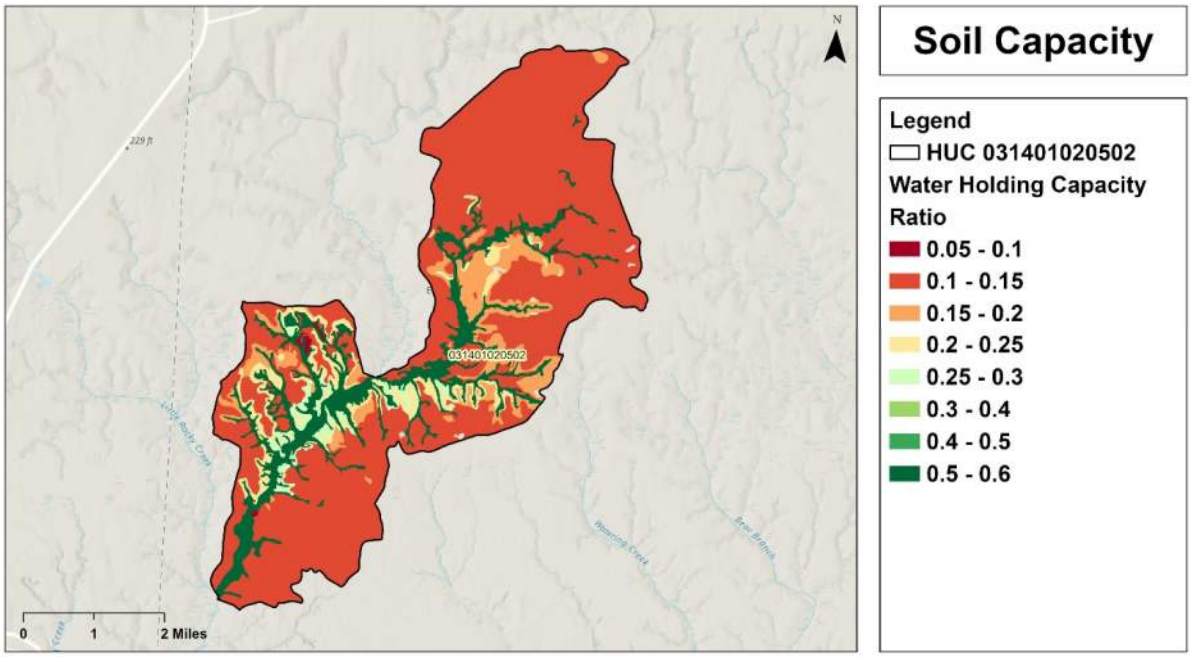

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020502, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

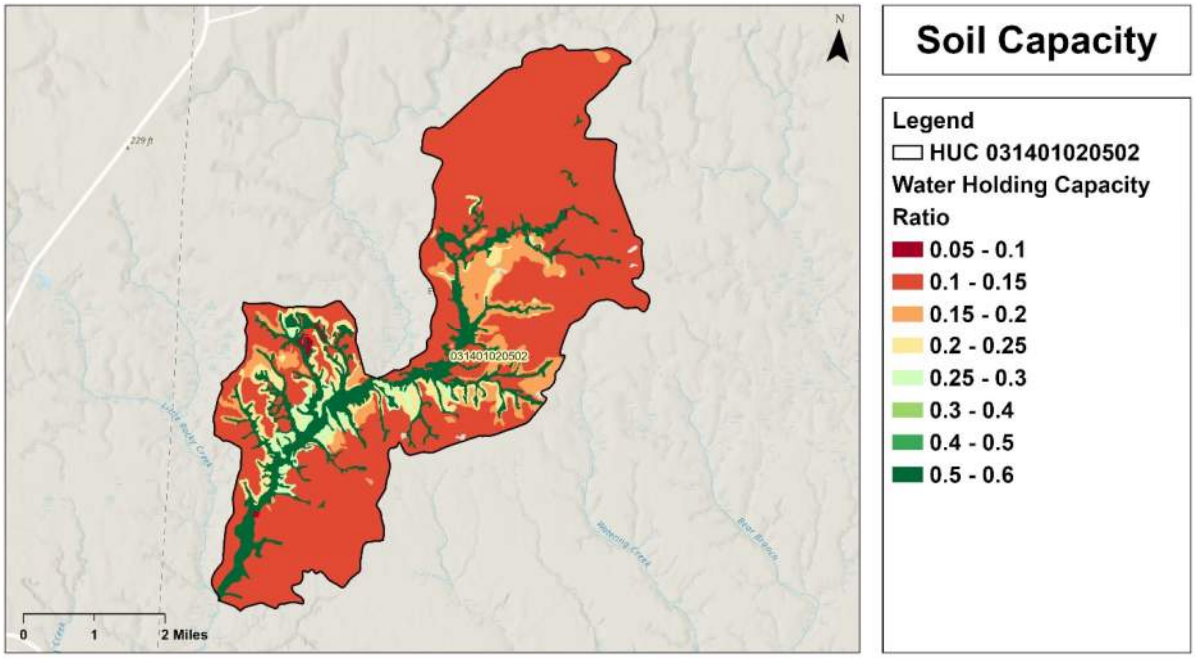

Figure 19. Land use in the HUC 031401020502 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

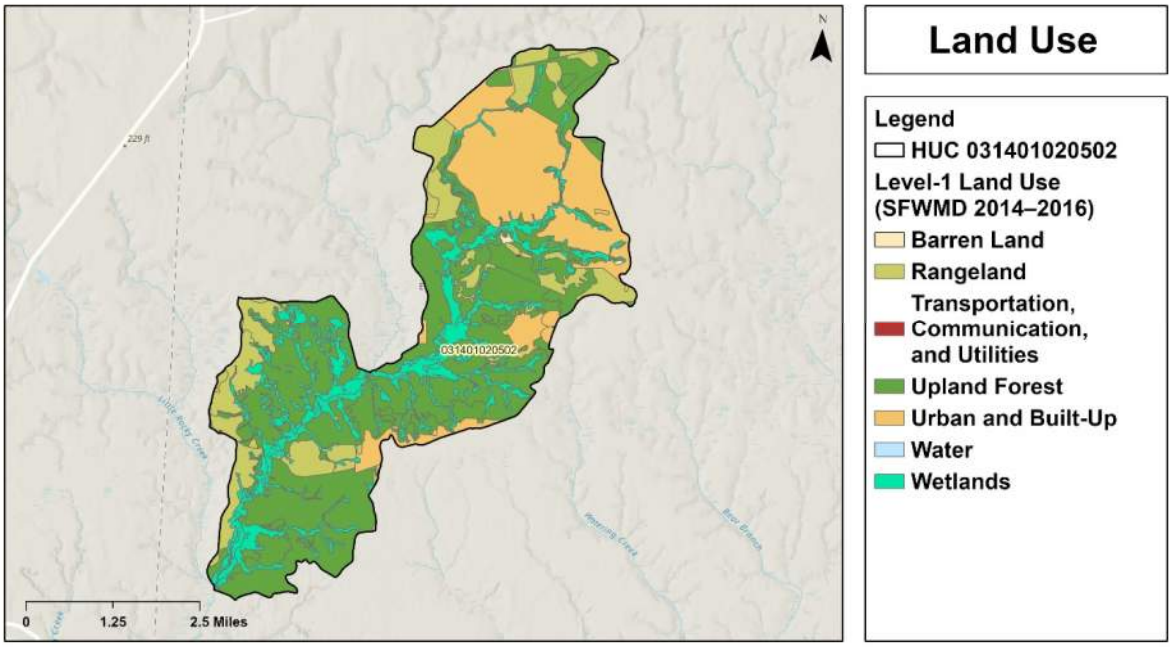

Figure 20. Land use in the HUC 031401020502 (from the (2023 Florida Geographic Data Library (FGDL)), processed by FAU.

In the HUC 031401020502 sub-watershed, the predominant land cover is upland forest, accounting for 54.06% of the area. Urban and built-up comes in second at 17.60%, followed by rangeland at 17.53%, and wetlands at 10.52%, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401020502 subwatershed (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	0.00	0.00%
Barren Land	26.46	0.12%
Rangeland	3994.12	17.53%
Transportation, Communication, and Utilities	3.42	0.01%
Upland Forest	12313.66	54.06%
Urban and Built-Up	4008.33	17.60%
Water	37.96	0.17%
Wetlands	2395.47	10.52%
Grand Total:	**22779.43**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

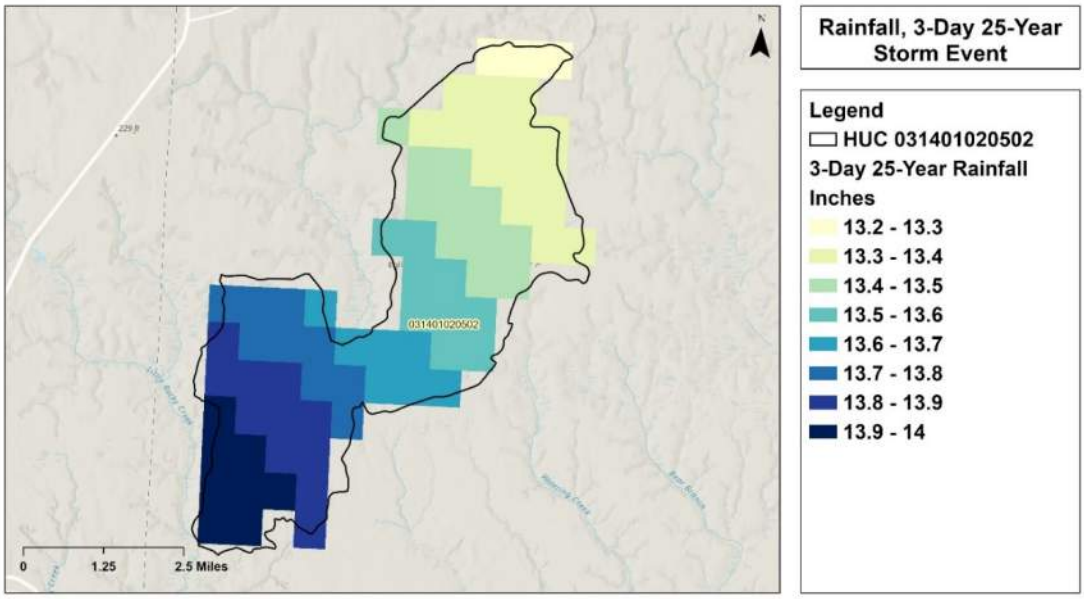

Figure 21. Rainfall distribution map across HUC 031401020502 sub-watershed, for 3-day 25-year storm event, processed by FAU.

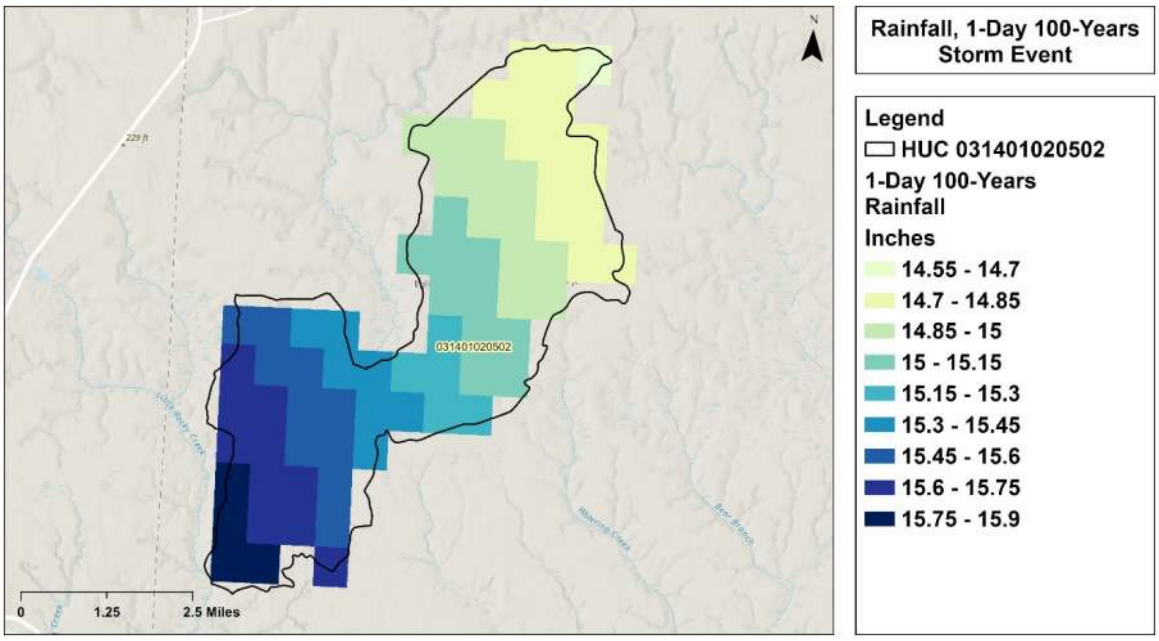

Figure 22. Rainfall distribution map across HUC 031401020502 sub-watershed, for 1-day 100-year storm event, processed by FAU.

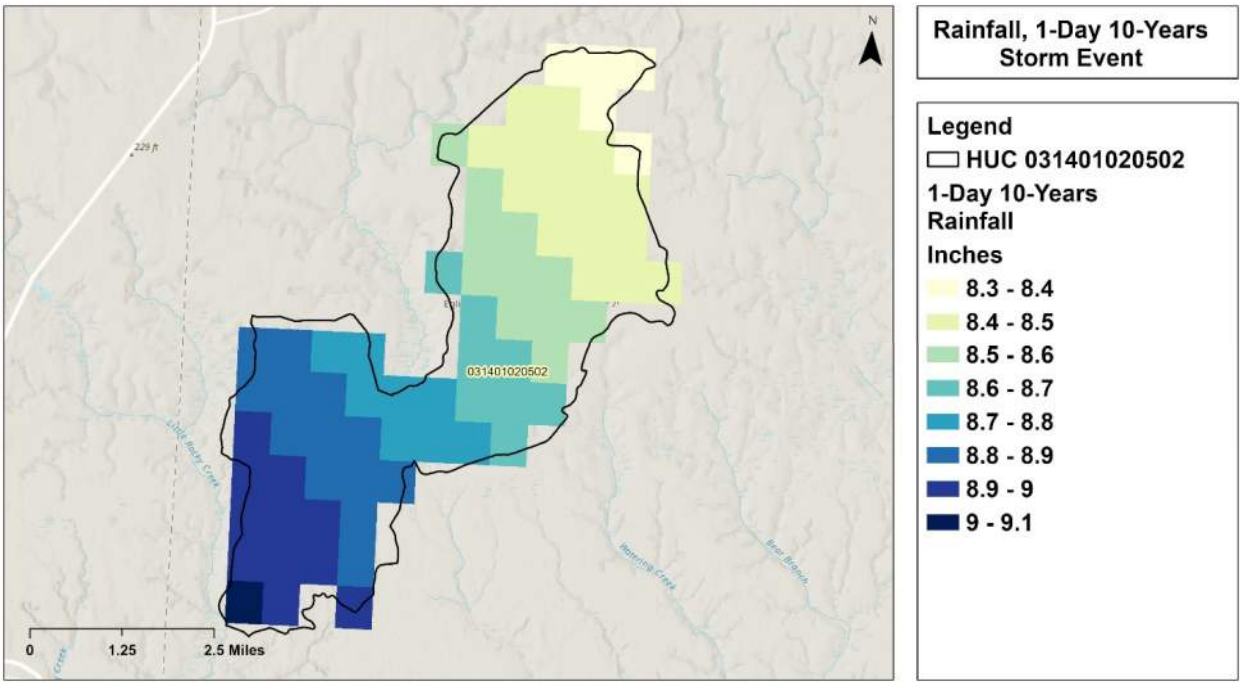

Figure 23. Rainfall distribution map across HUC 031401020502 sub-watershed, for 1-day 10-year storm event, processed by FAU.

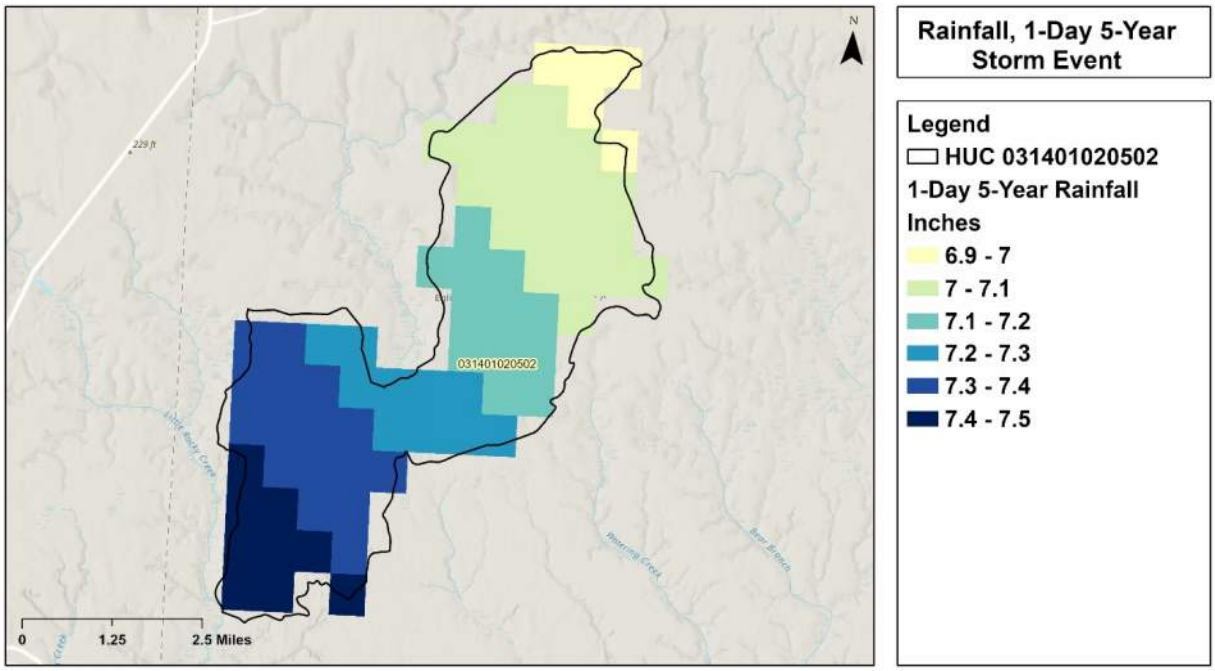

Figure 24. Rainfall distribution map across HUC 031401020502 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer

was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

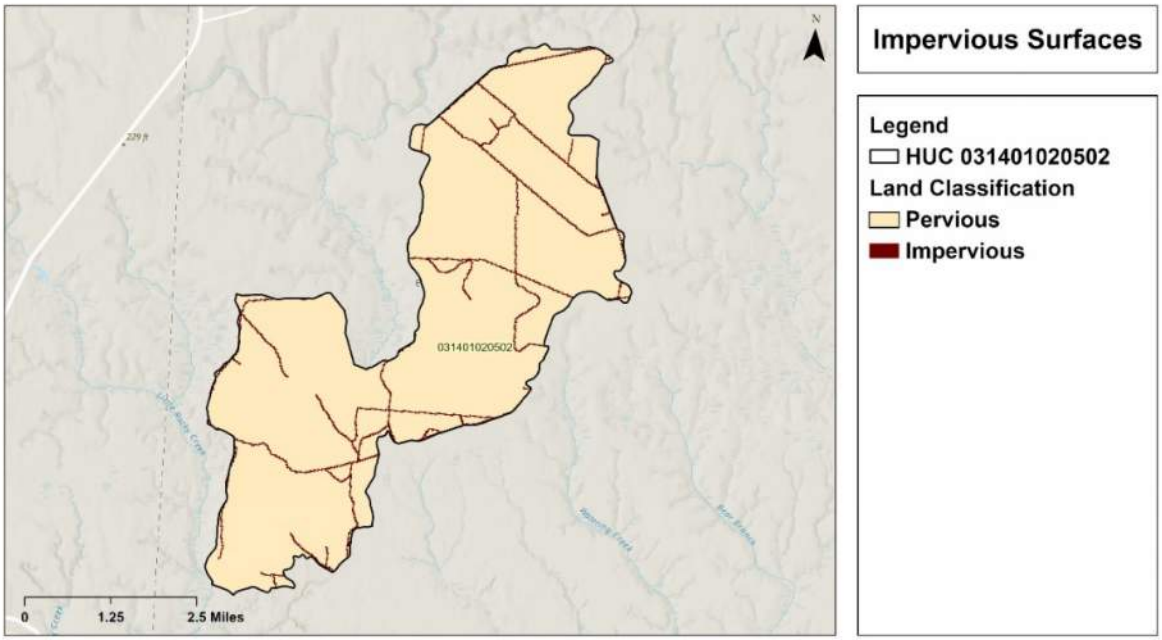

Figure 25. Impervious area map for the HUC 031401020502 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

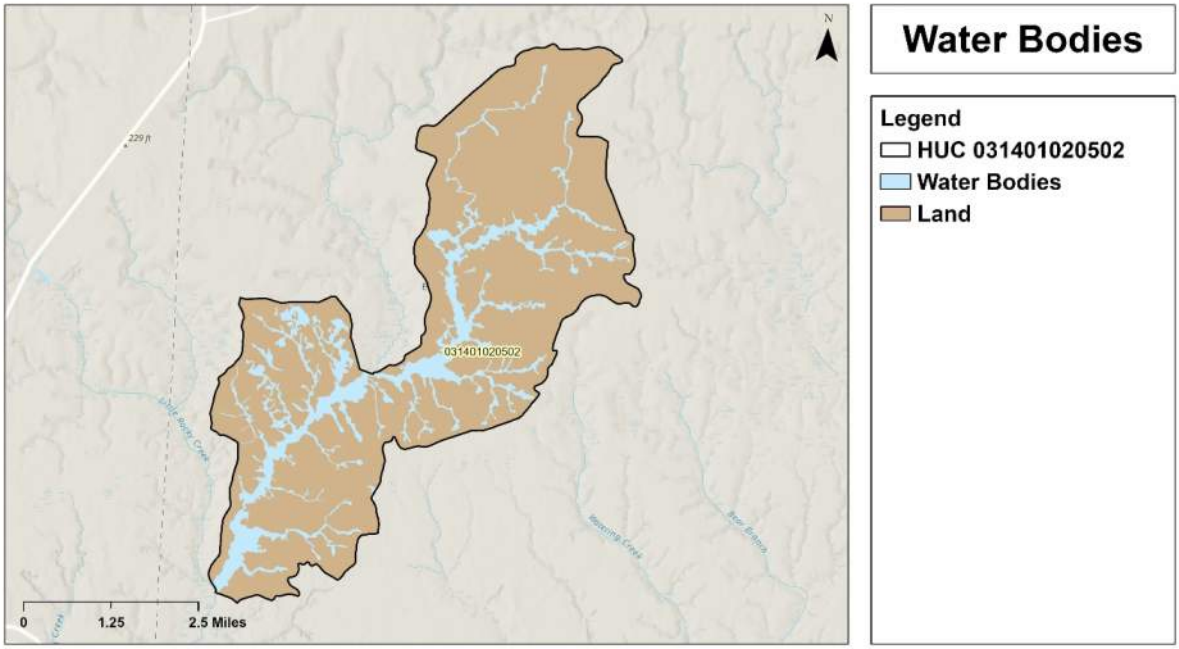

Figure 26. Water bodies map for the HUC 031401020502 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

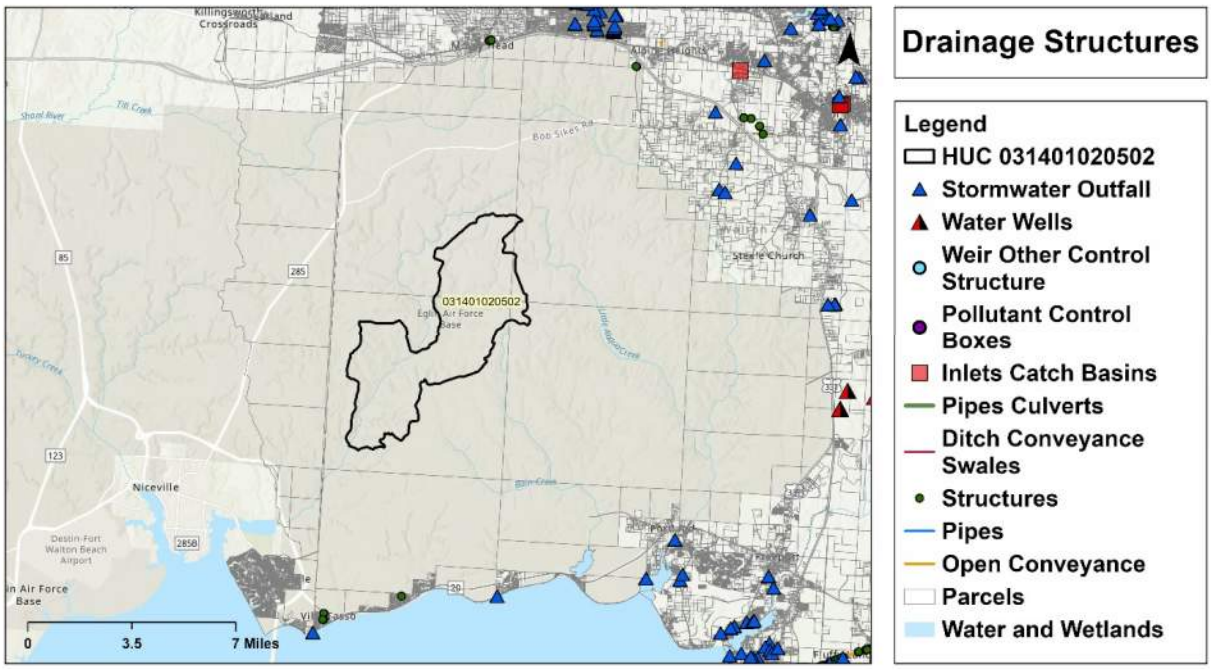

Figure 27. Stormwater Infrastructure for the HUC 031401020502. Processed by FAU.

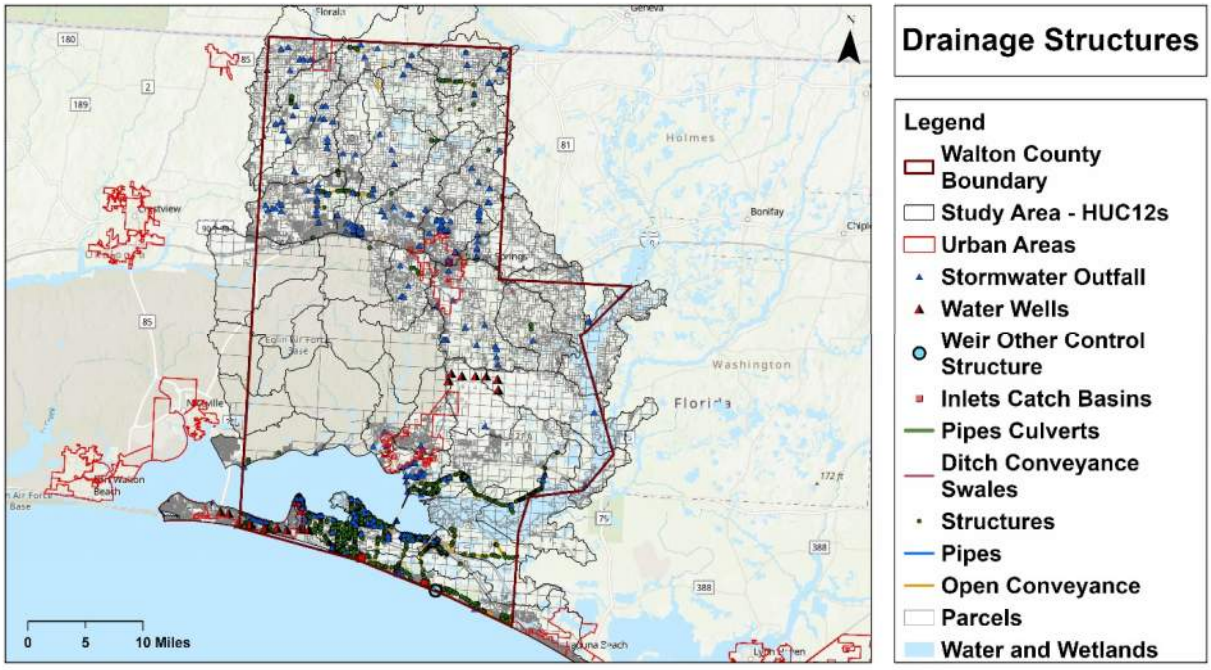

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**.. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020502 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species

while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

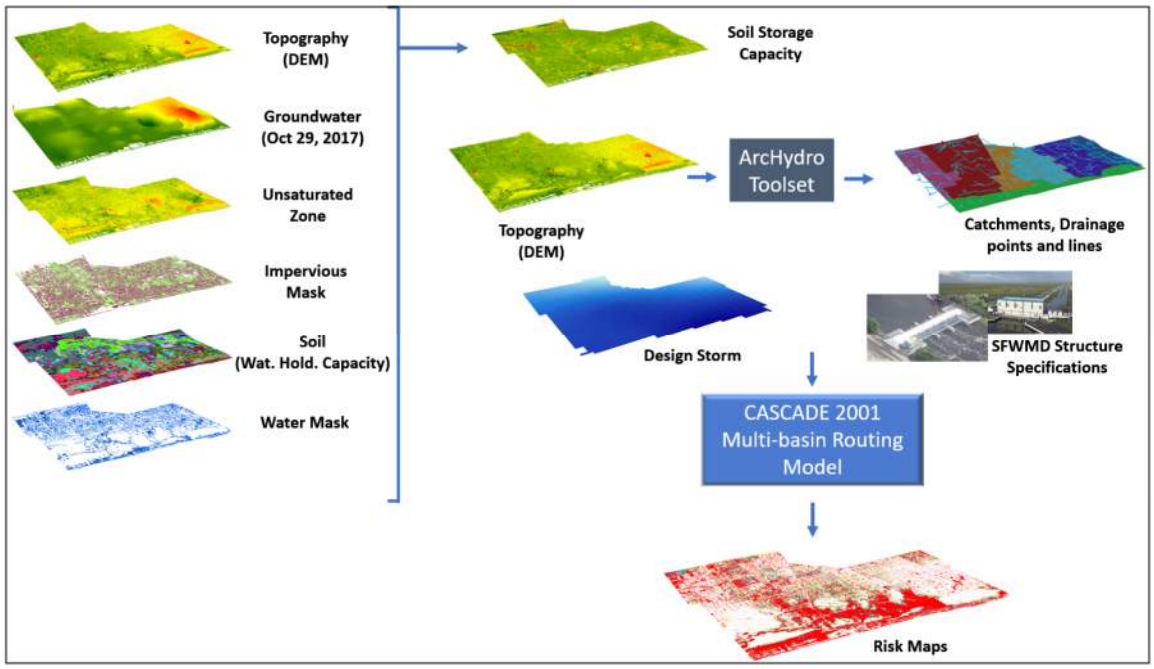

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

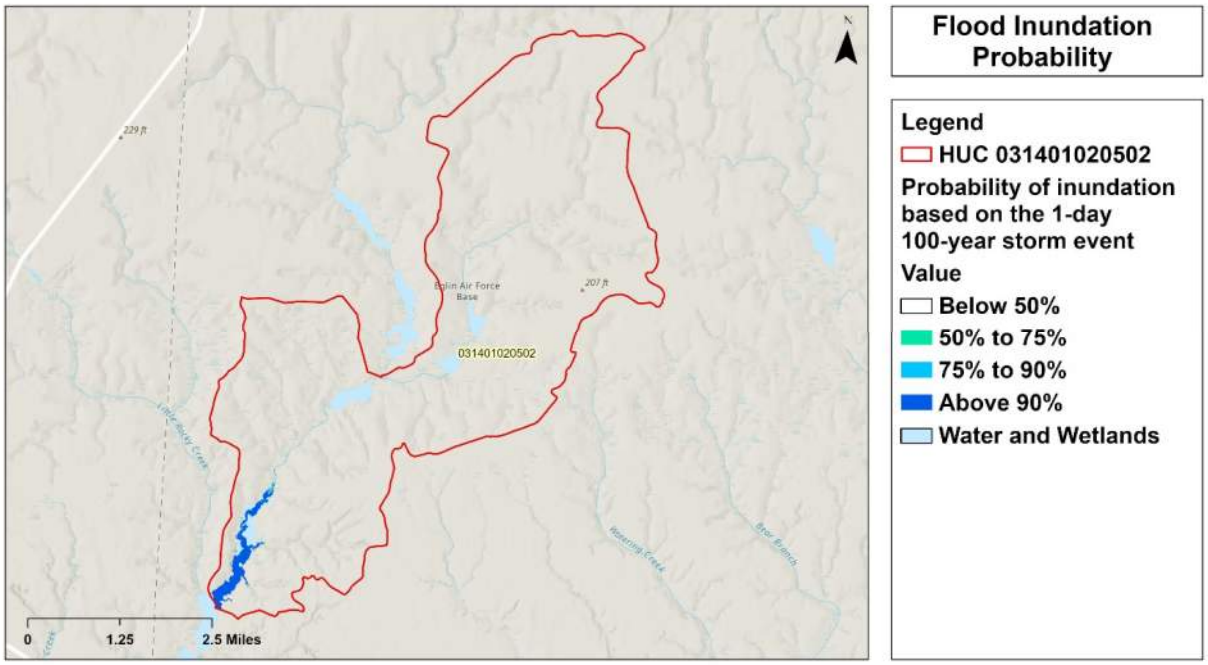

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020502, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate

the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.9% of the HUC total area or 0.19 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 1% of the HUC's total area, or 0.22 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.5% of the HUC's total area, or 0.12 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.5% of the HUC's total area, or 0.11 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401020502 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	20.78	0.19	99.1%	0.9%
1-day 100-year	20.76	0.22	99.0%	1.0%
1-day 10-year	20.86	0.12	99.5%	0.5%
1-day 5-year	20.86	0.11	99.5%	0.5%

Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations.
Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5

70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401020502 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020502. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020502. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020502	13421.71
All of the 1-day 100-year storm event inundation	**138.04**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	85.11
B. Federal Land in 1-day 100-year inundation > 10 acres	52.92
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	0.00
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	0.00

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that

have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

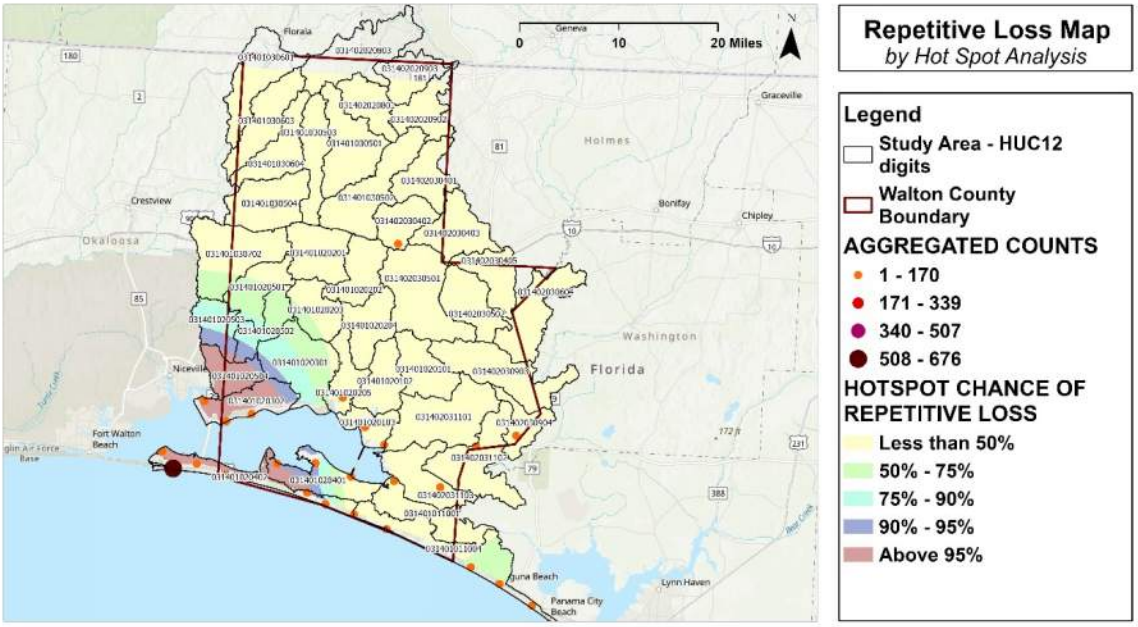

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

The entire HUC area is undeveloped and non-coastal. As a result, there are no critical facilities or other land uses that require priority intervention. The minor flooding and null composite score indicate that the HUC is not significantly affected by flooding, and there are no pressing priorities for interventions to address inundation impacts.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020503) is highlighted among all the HUCs to help identifying its location. (Figure 3).

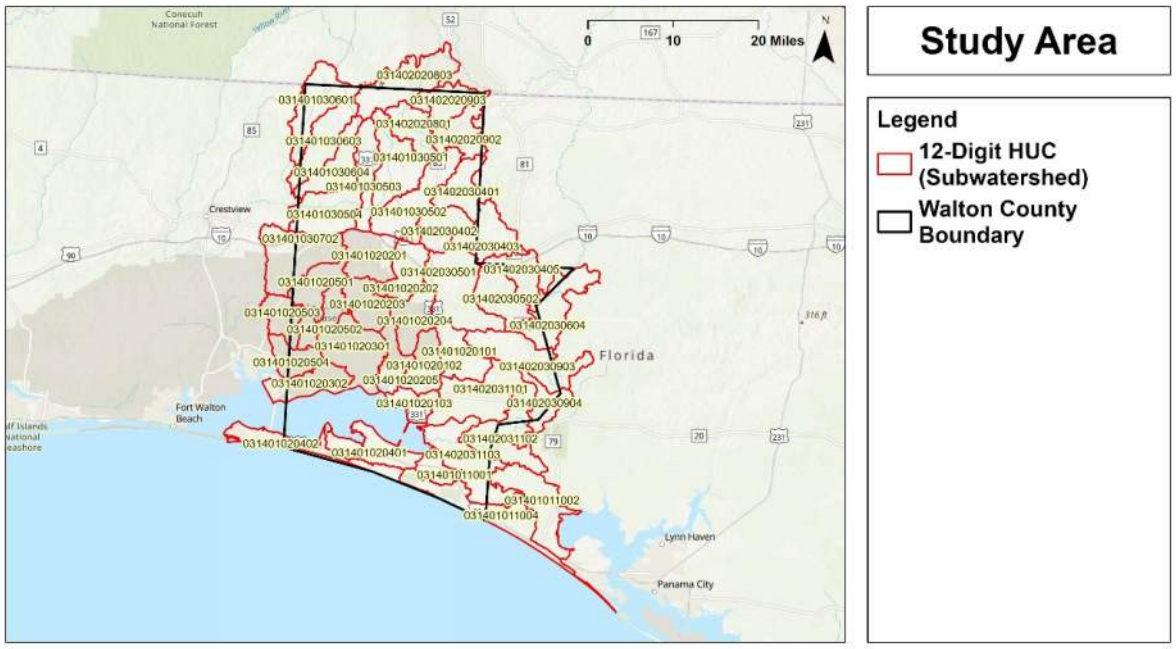

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

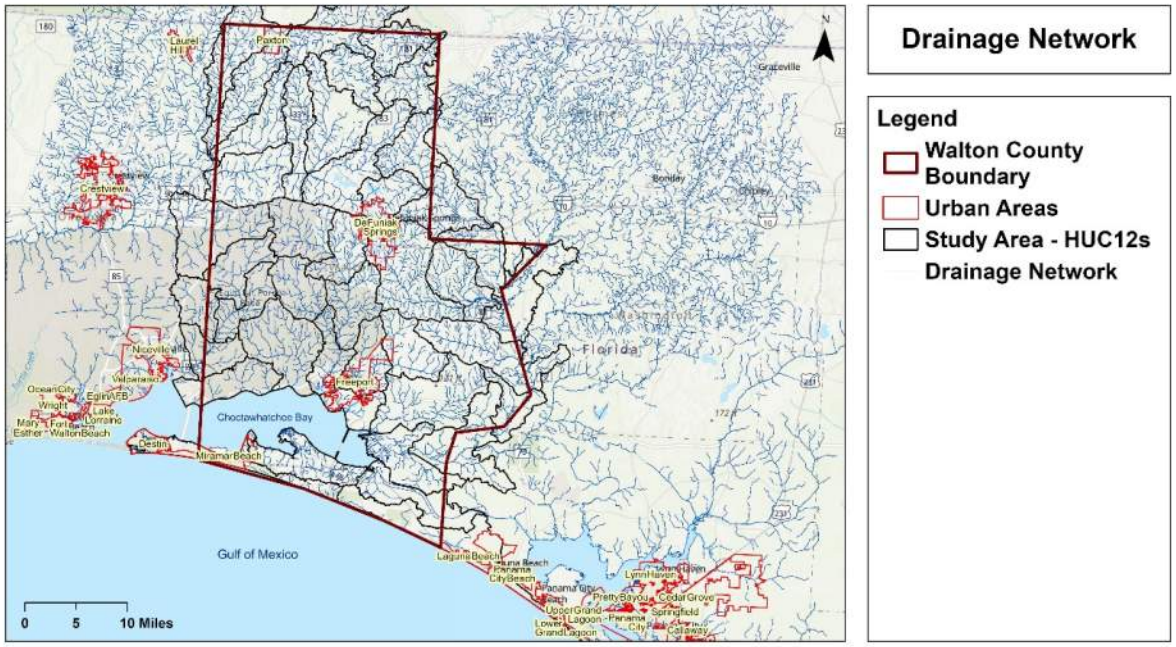

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

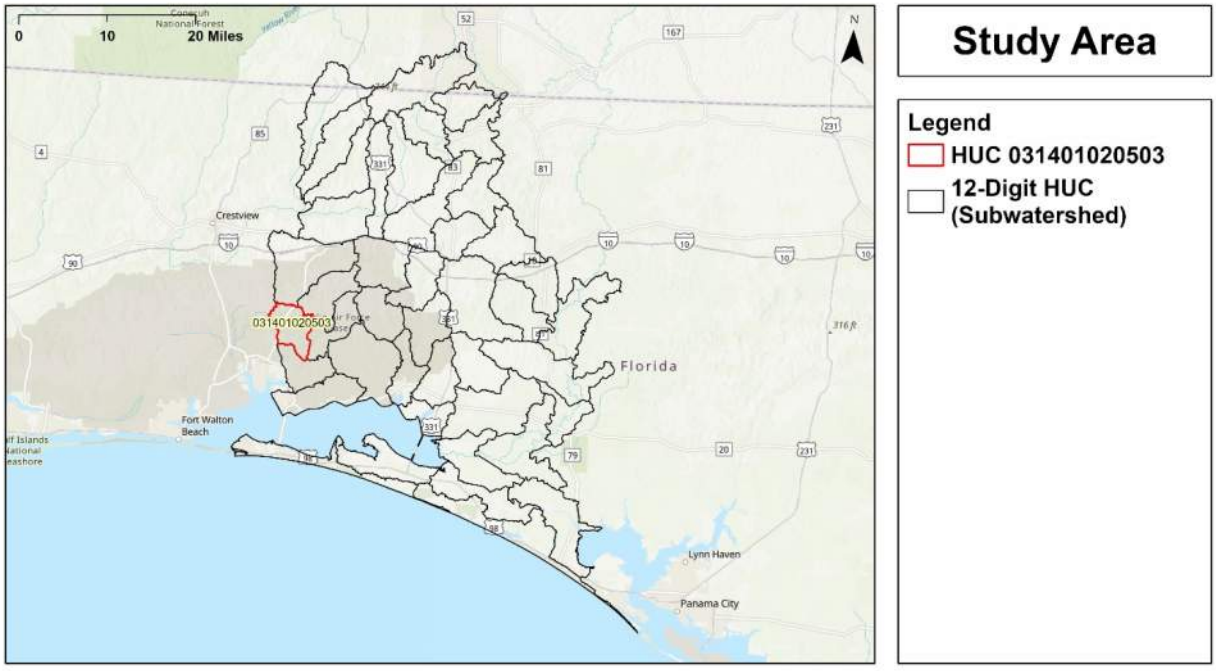

Figure 3. HUC 031401020503 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the 2014-2016 SFWMD Level 1 land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

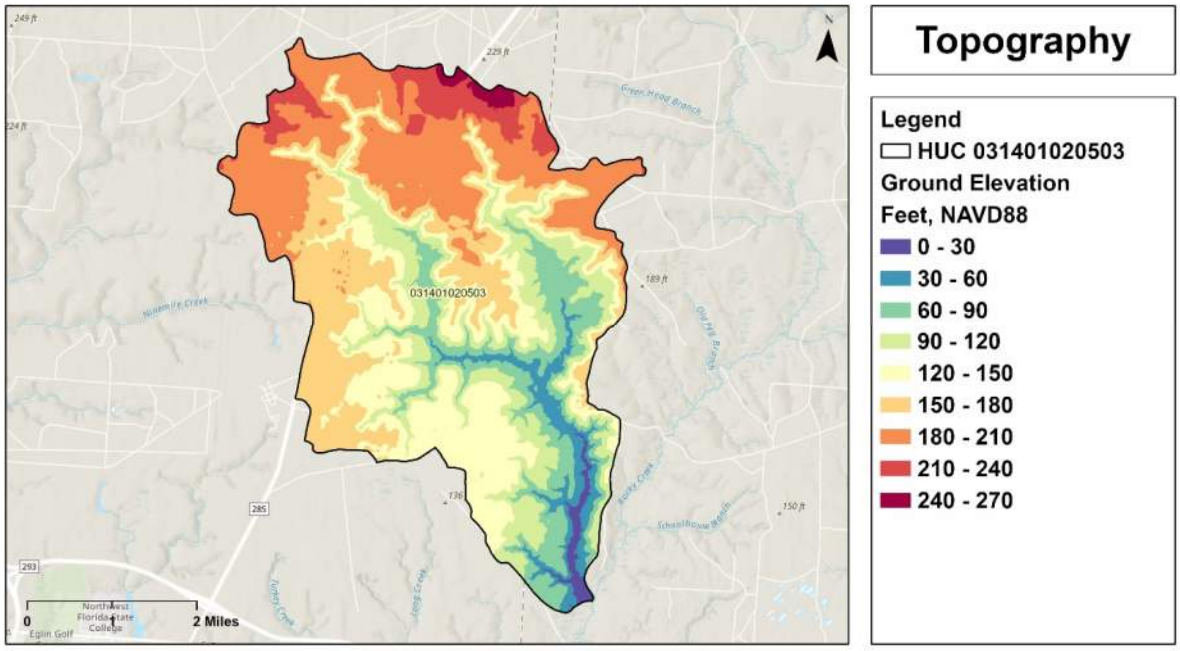

Figure 4. Topographic map of the HUC 031401020503 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.

Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020503 sub-watershed is shown in **Error! Reference source not found.**.

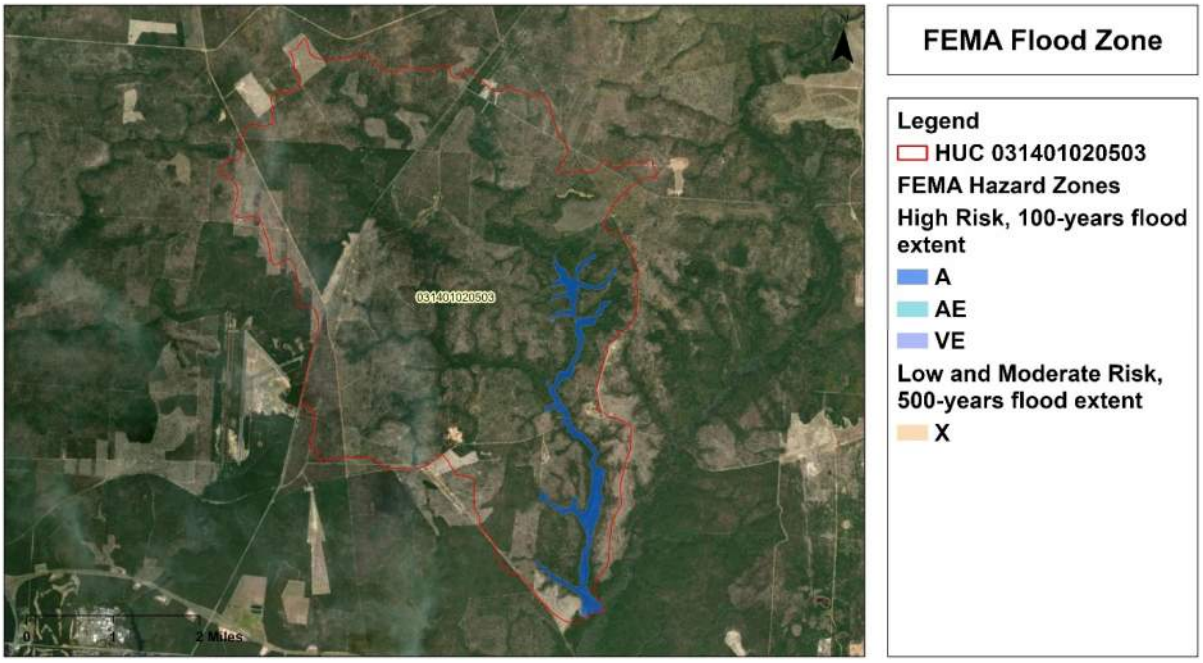

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020503 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination

between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401020503 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

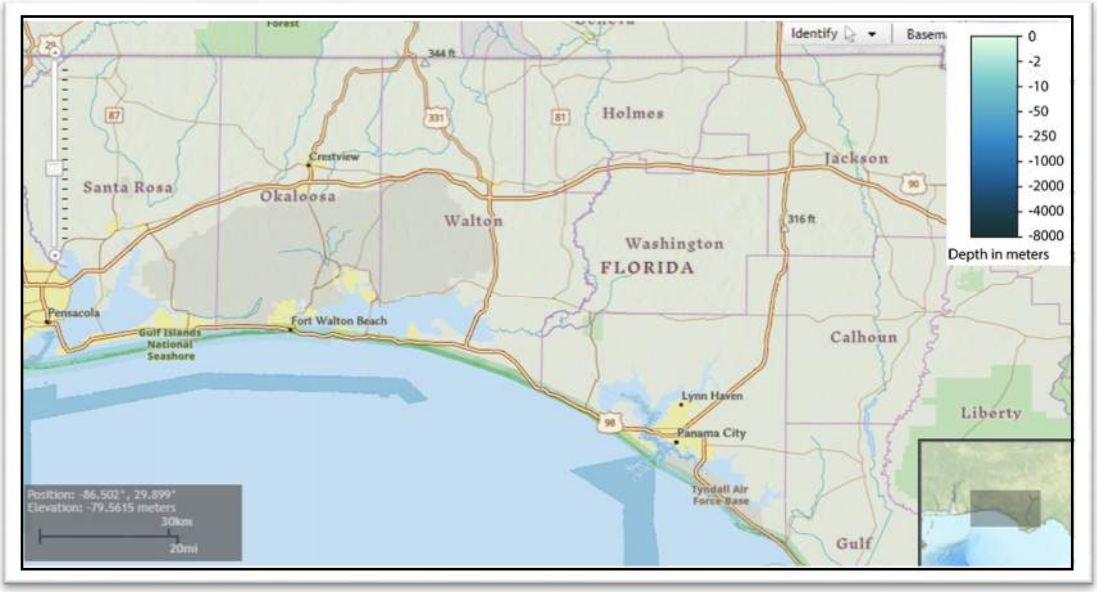

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

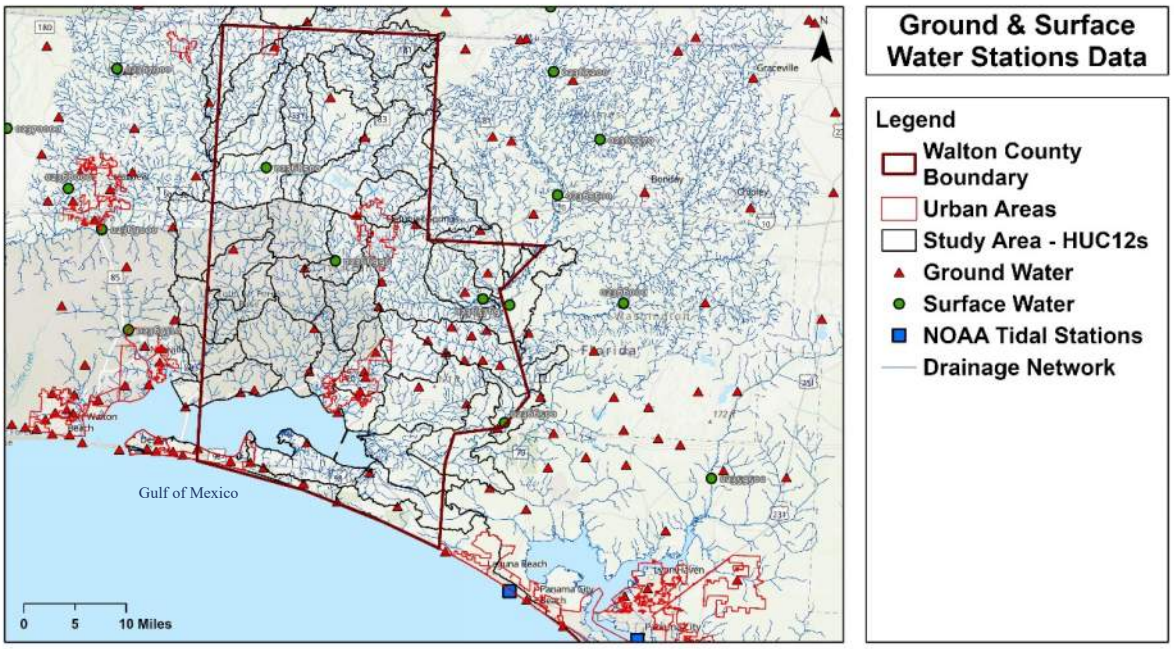

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401020503 has no major rivers and canals, but creeks and a branch, include:

- Little Rocky Creek
- Smith Branch
- Middle Rocky Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366996. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401020503, which is USGS 02366996 Alaqua Creek Near Pleasant Ridge, FL.

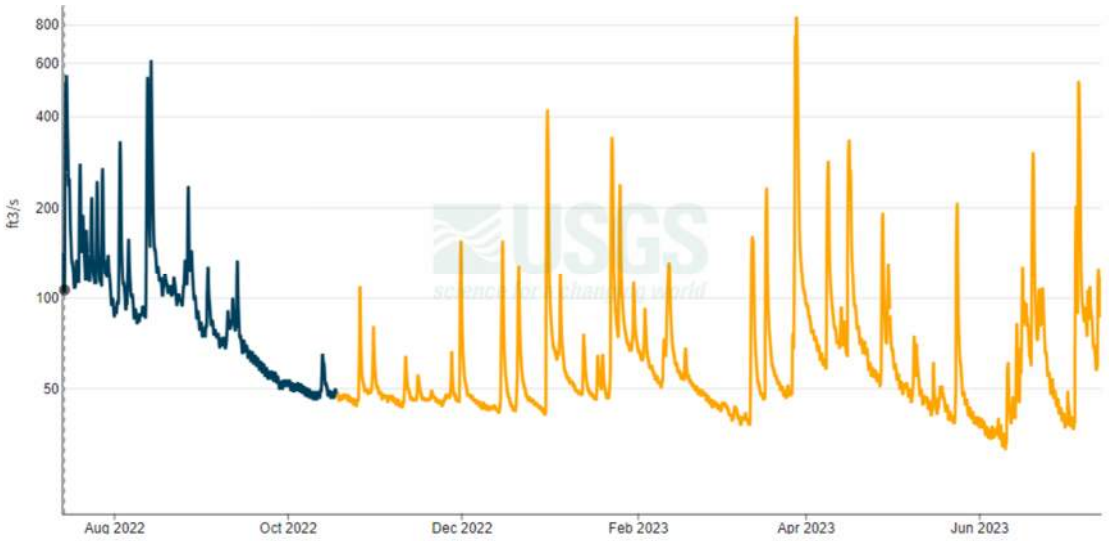

Figure 8. Average streamflow for Alaqua Creek Near Pleasant Ridge, FL (USGS 02366996 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366996/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99^{th}- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98^{th} - 100^{th} percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data is obtained from the SFWMD DBHYDRO site for surface waters (https://www.sfwmd.gov/science-data/dbhydro) and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401020503 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020503 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

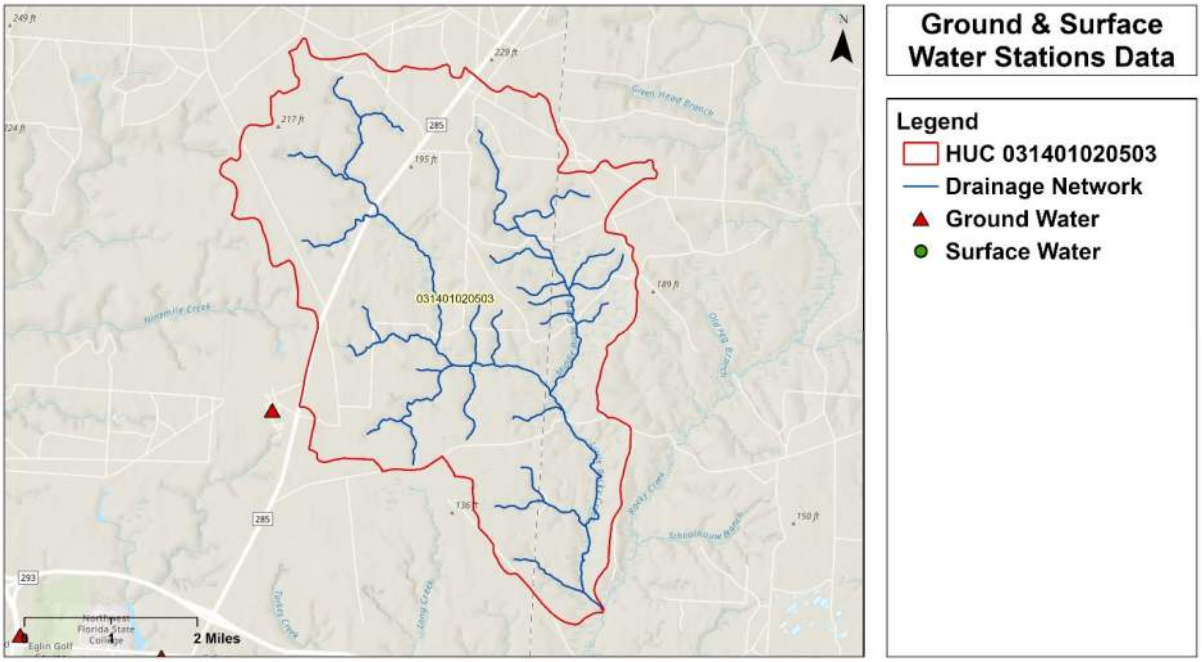

Figure 9. Ground and Surface Water Stations in the HUC 031401020503 sub-watershed, processed by FAU.

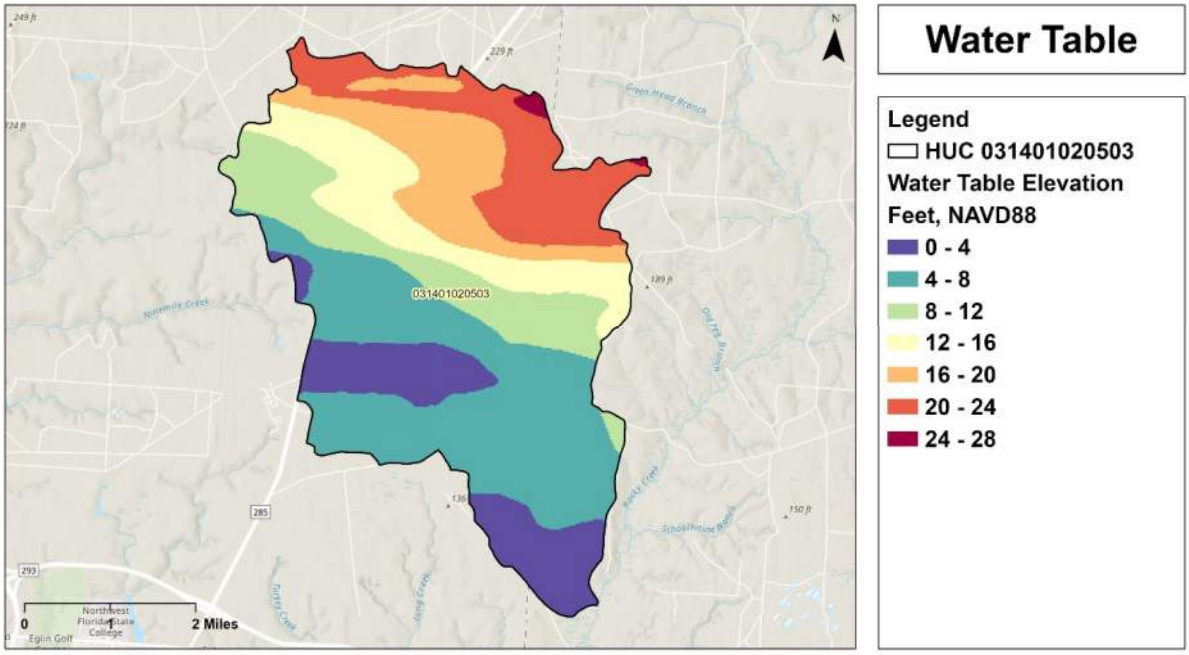

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020503 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

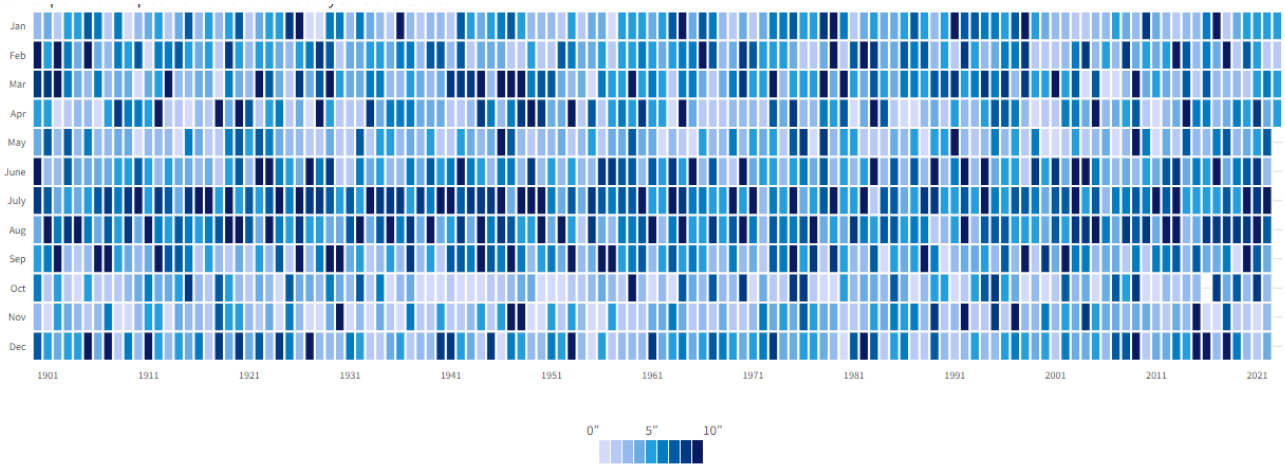

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

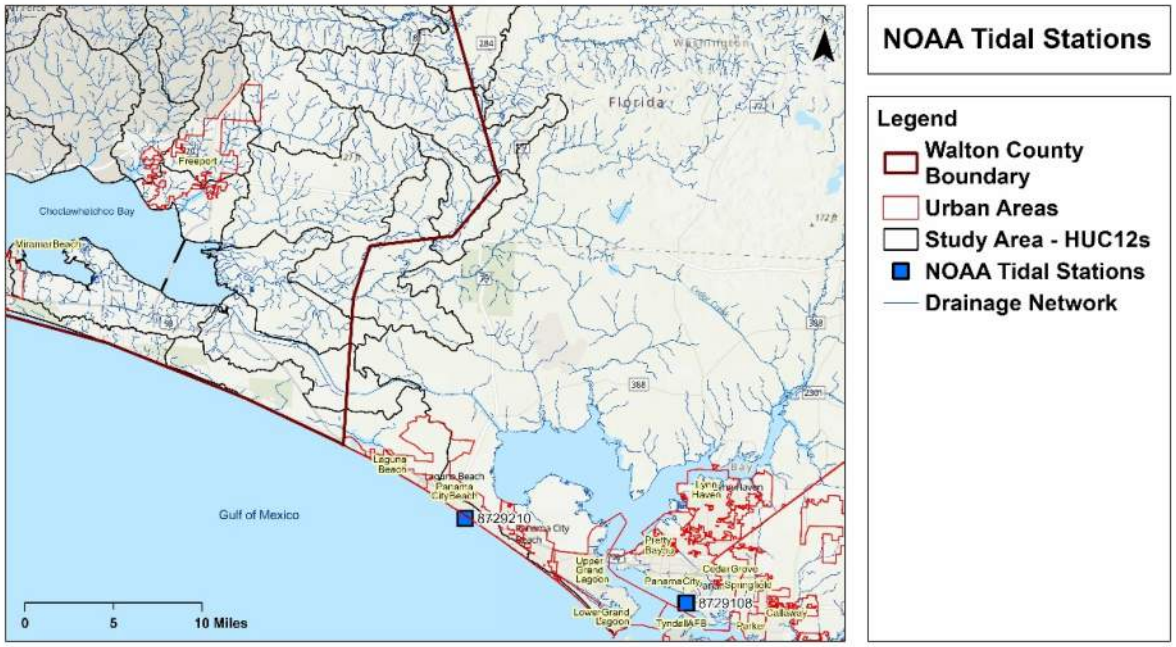

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

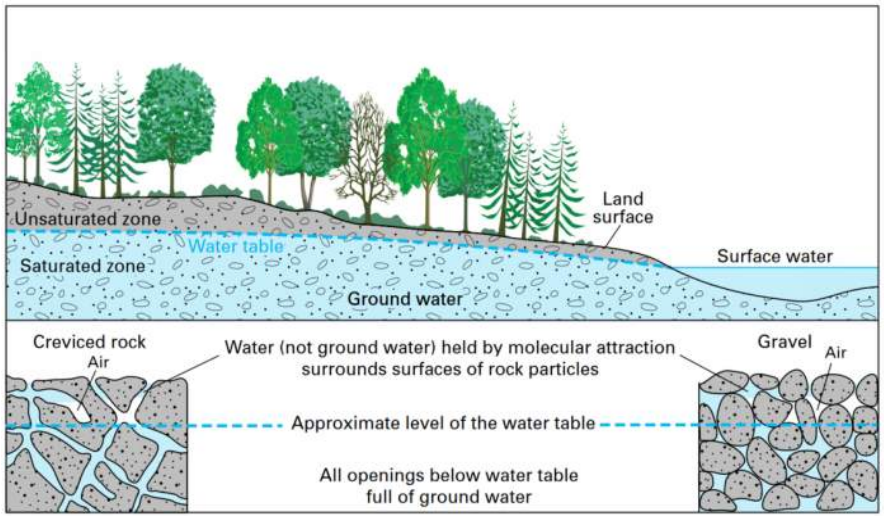

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

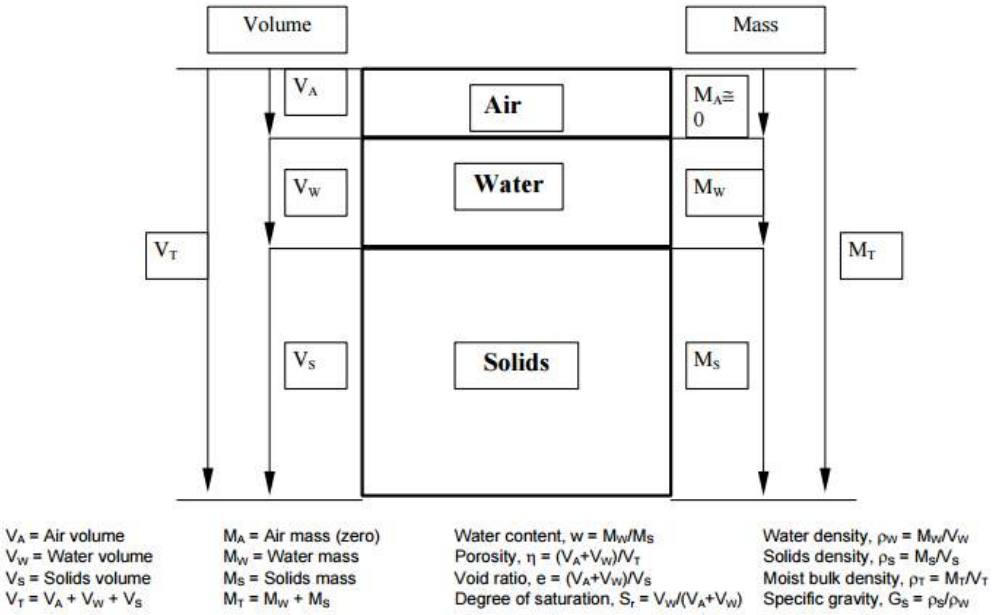

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

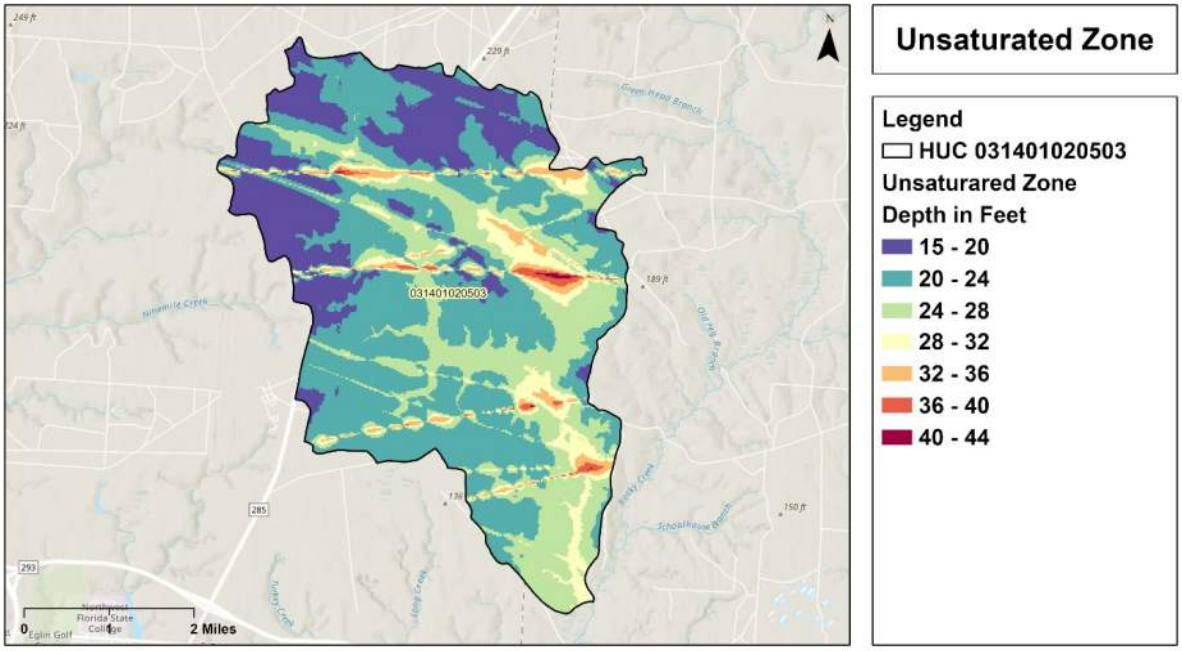

Figure 15. Unsaturated zone map for HUC 031401020503, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin demonstrates a limited to moderate soil storage capacity, falling within the range of 15 to 32 feet of remaining capacity.

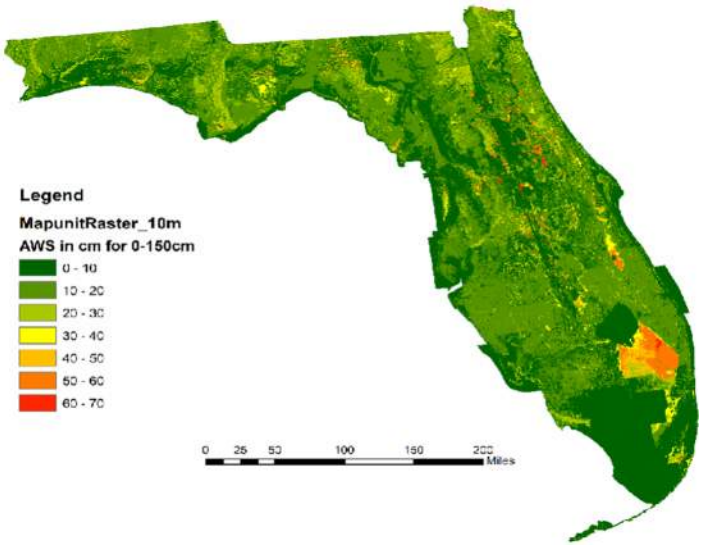

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

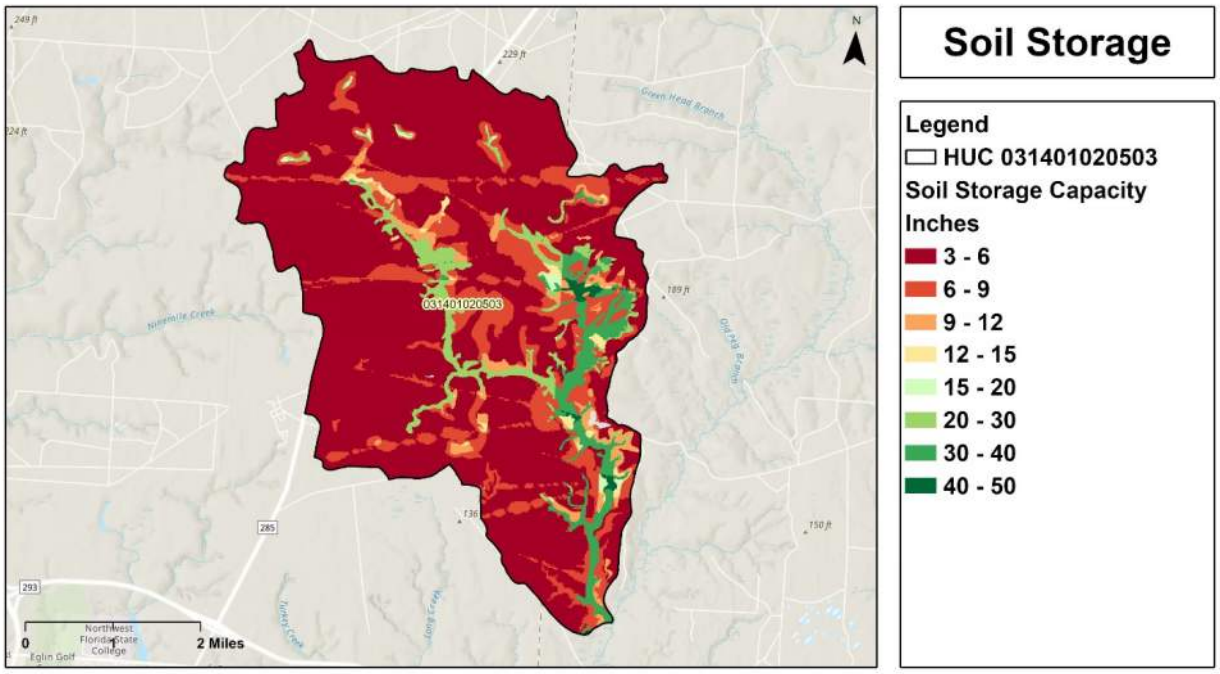

Figure 17. Water storage capacity of soil for the HUC 031401020503, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

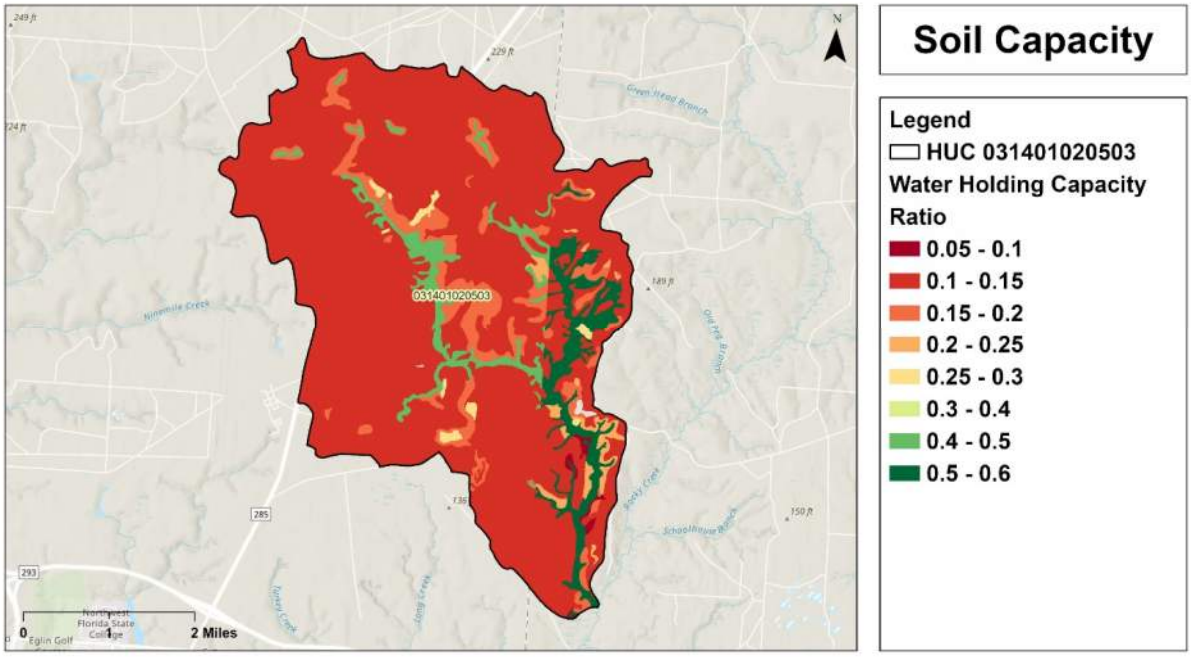

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020503, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

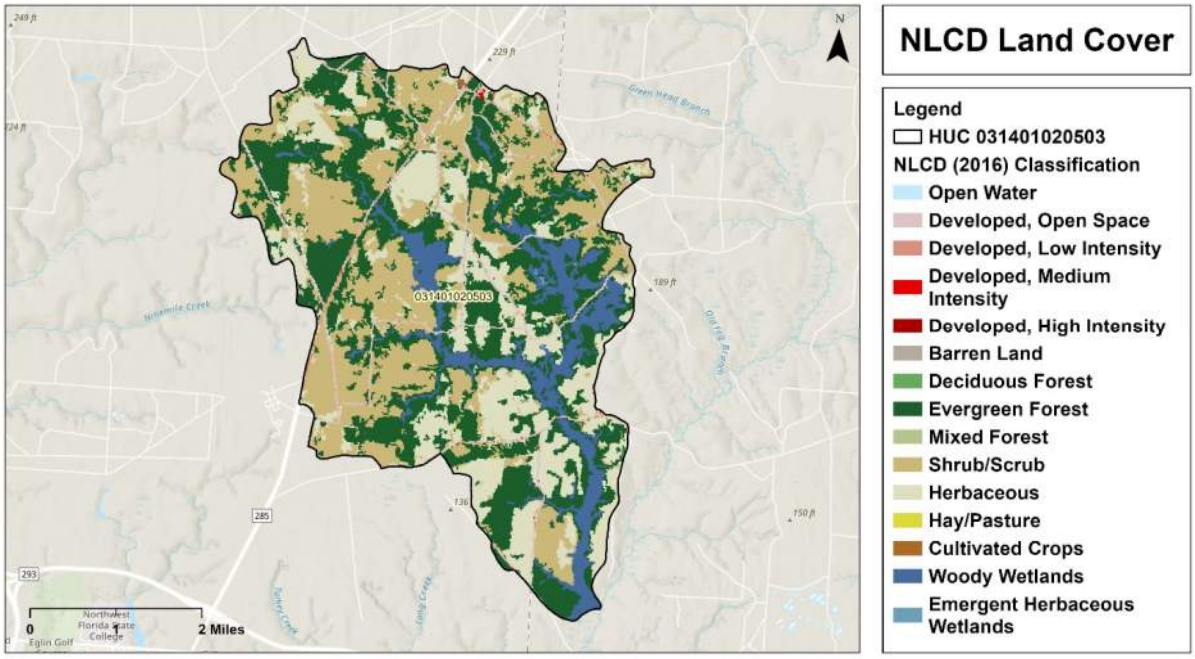

Figure 19. Land use in the HUC 031401020503 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

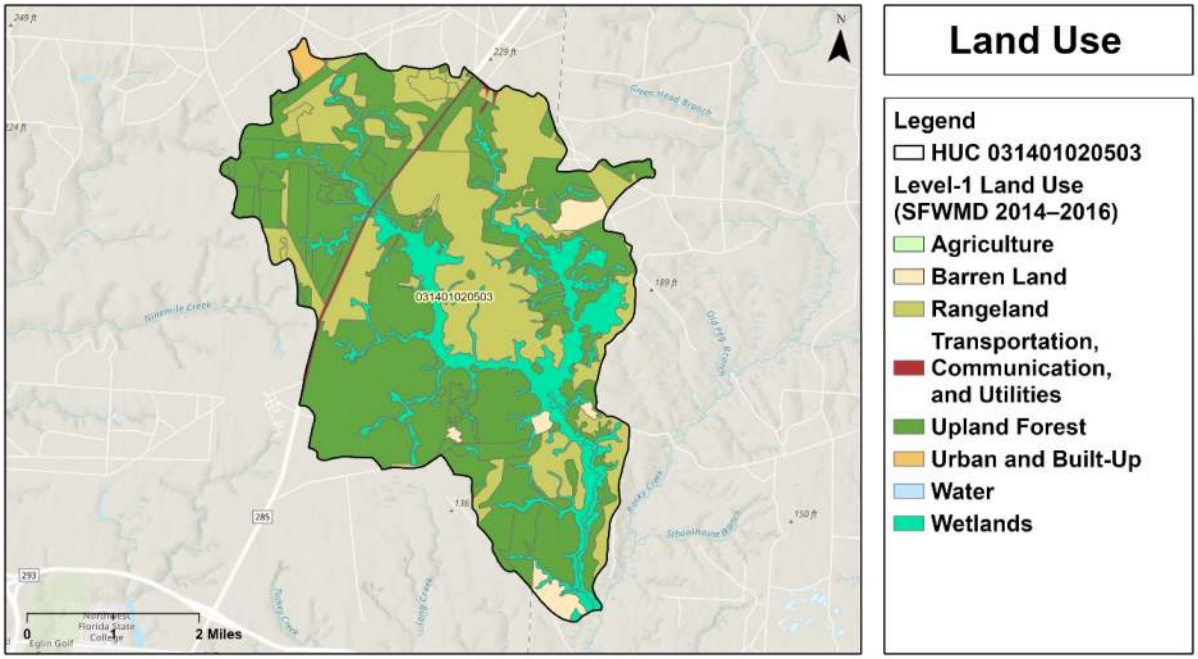

Figure 20. Land use in the HUC 031401020503 (SFWMD 2014-2016), processed by FAU.

In the HUC 031401020503 sub-watershed, the predominant land cover is upland forest, accounting for 45.19% of the area. Rangelands comes in second at 32.56%, followed by Transportation, Communication, and Utilities at 11.44%, and wetlands at 9.10%. Developed land constitutes a minor portion, with only 0.39% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401020503 subwatershed (SFWMD 2014-2016).

Level 1 Land Use Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	0.00	0.00%
Barren Land	323.67	1.32%
Rangeland	7972.54	32.56%
Transportation, Communication, and Utilities	2801.00	11.44%
Upland Forest	11063.25	45.19%
Urban and Built-Up	95.52	0.39%
Water	0.00	0.00%
Wetlands	2228.30	9.10%
Grand Total:	**24484.27**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

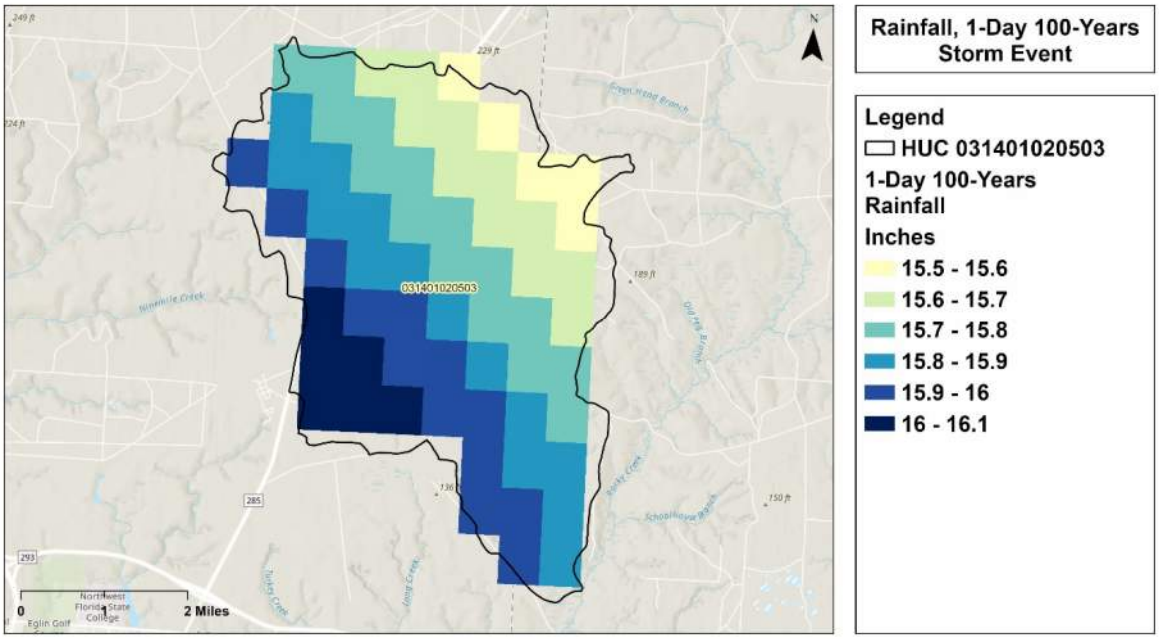

Figure 22. Rainfall distribution map across HUC 031401020503 sub-watershed, for 1-day 100-year storm event, processed by FAU.

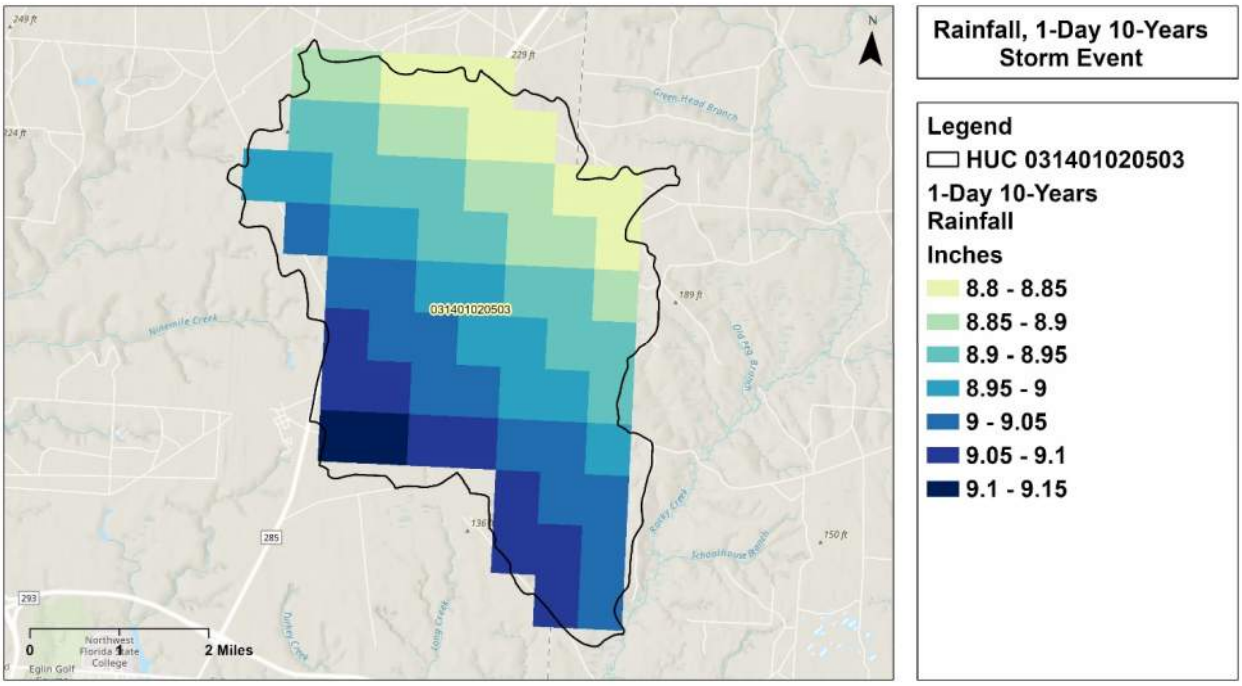

Figure 23. Rainfall distribution map across HUC 031401020503 sub-watershed, for 1-day 10-year storm event, processed by FAU.

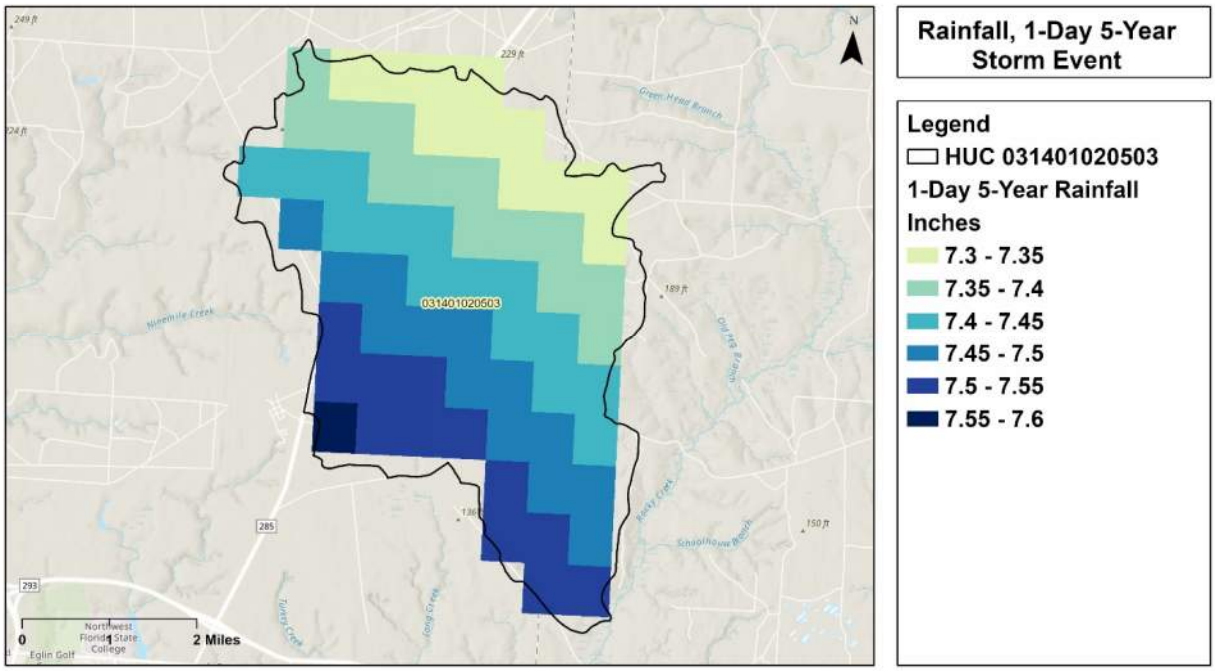

Figure 24. Rainfall distribution map across HUC 031401020503 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer

was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

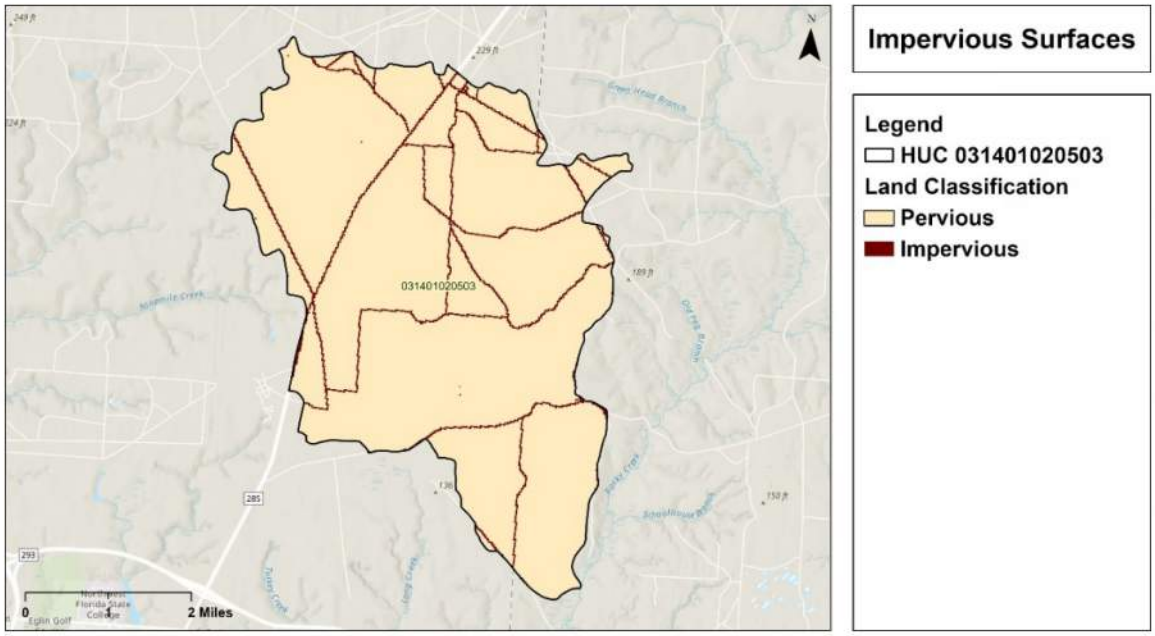

Figure 25. Impervious area map for the HUC 031401020503 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

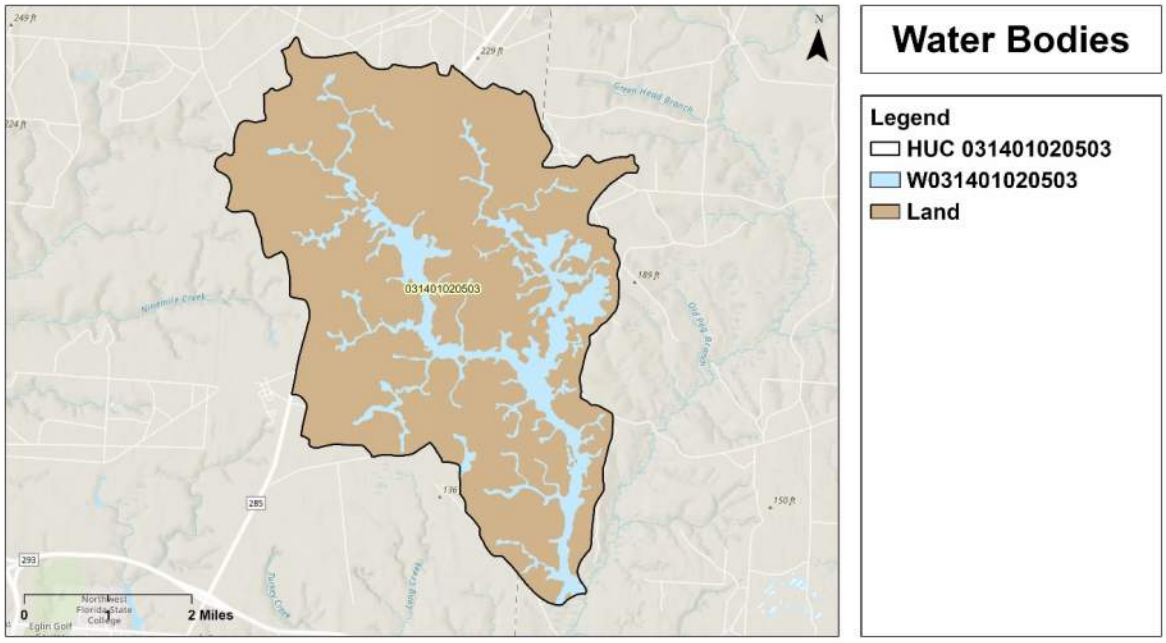

Figure 26. Water bodies map for the HUC 031401020503 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, , such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

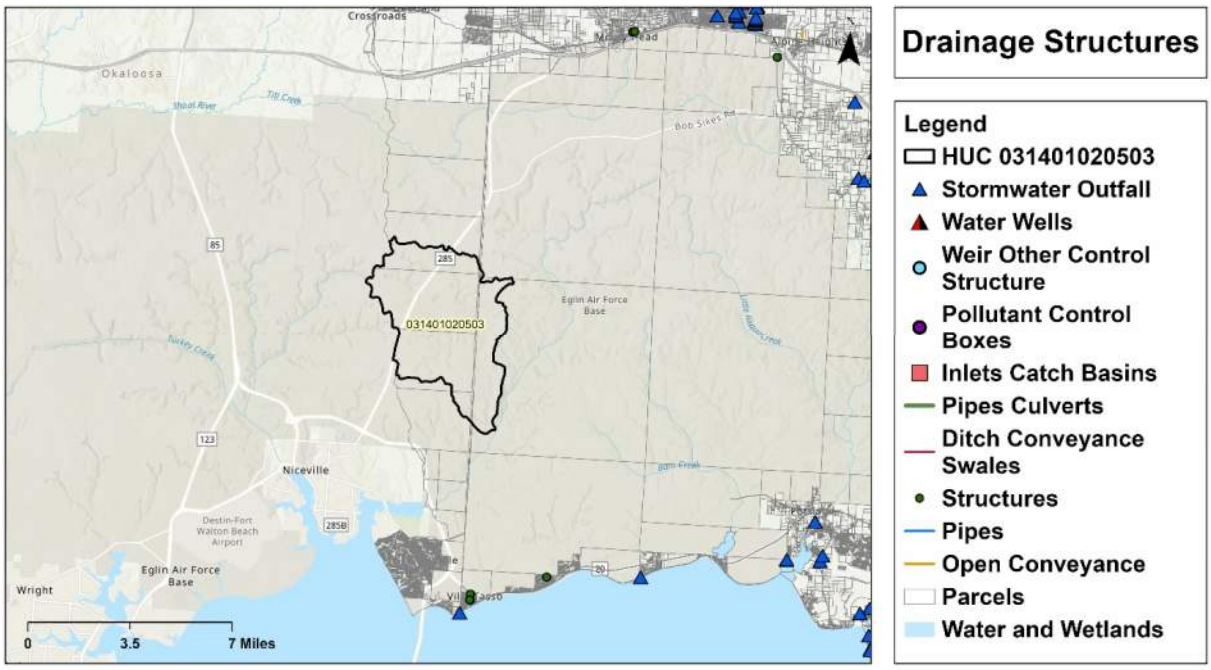

Figure 27. Stormwater Infrastructure for the HUC 031401020503. Processed by FAU.

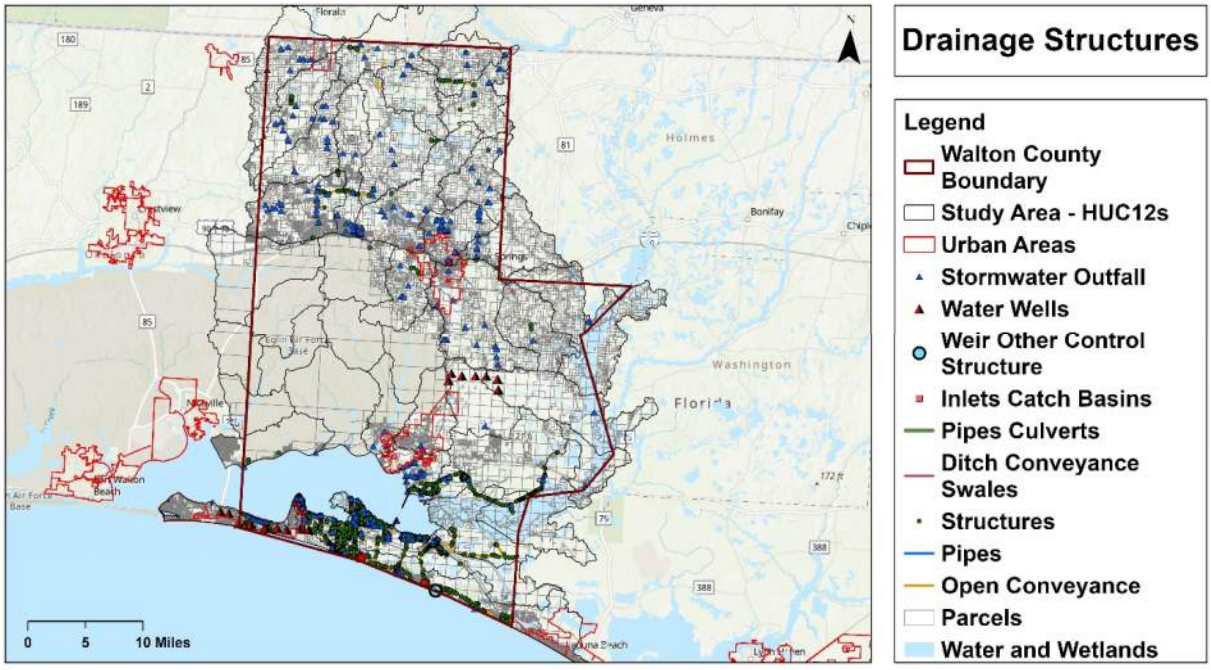

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**.. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020503 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the SFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

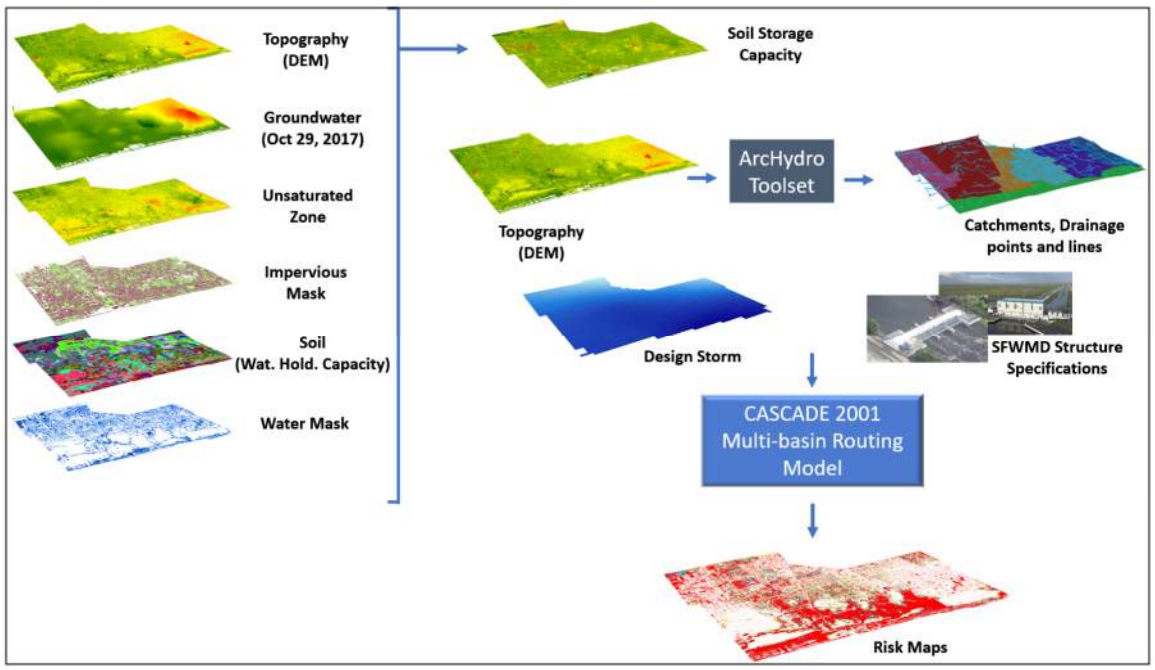

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

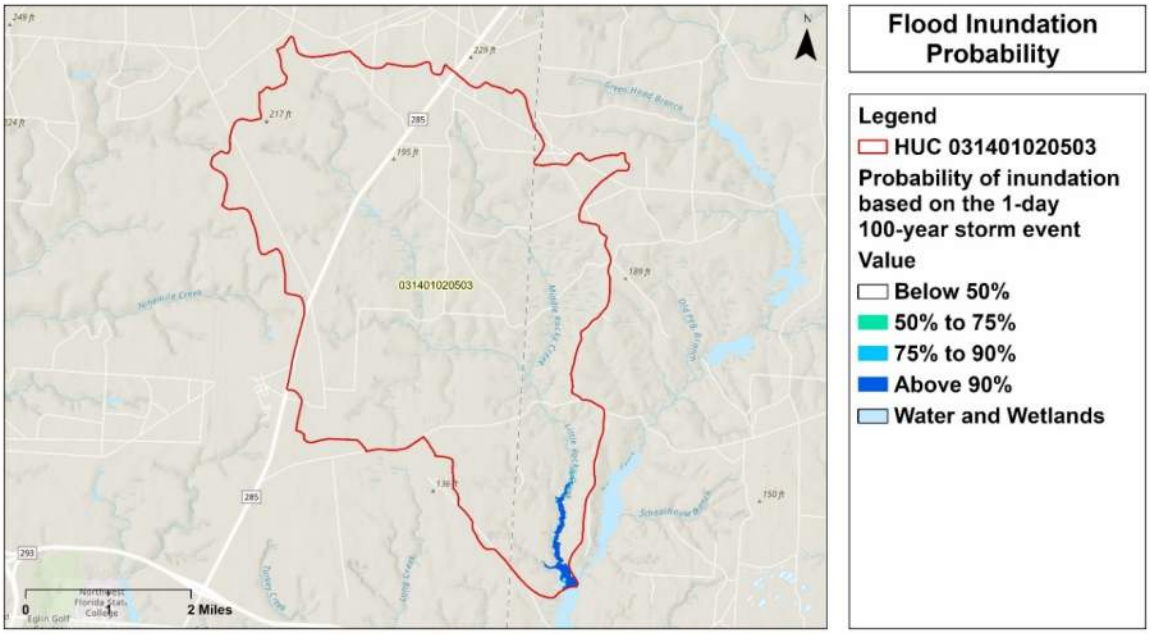

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020503, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees

and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.6% of the HUC total area or 0.11 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.6% of the HUC's total area, or 0.12 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.4% of the HUC's total area, or 0.08 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.3% of the HUC's total area, or 0.07 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401020503 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	19.15	0.11	99.4%	0.6%
1-day 100-year	19.14	0.12	99.4%	0.6%
1-day 10-year	19.18	0.08	99.6%	0.4%
1-day 5-year	19.19	0.07	99.7%	0.3%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. The major regional issues in the greater watershed are the C43 reservoir and capital projects associated with the SFWMD plans for controlling discharges that impact the ecosystem in the west end of the watershed. Hence regional water management districts and USACE projects have higher priority due the larger area served. All other improvements are distinctly local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	Description	TIER (Priority of Land Use)
0	Vacant Residential	6
1	Single Family Residential	5

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.**depict the HUC 031401020503 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

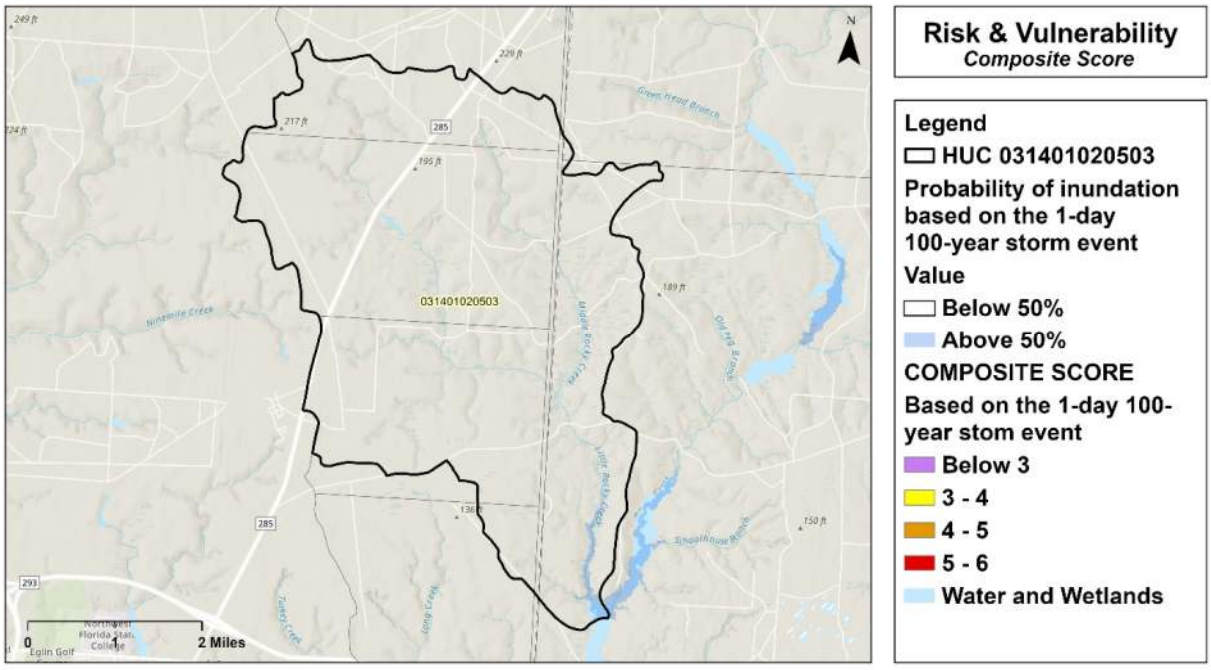

Figure 38. HUC 031401020503 sub-watershed Composite Score Risk map, calculation based on 1-day 100-year storm event. Processed by FAU.

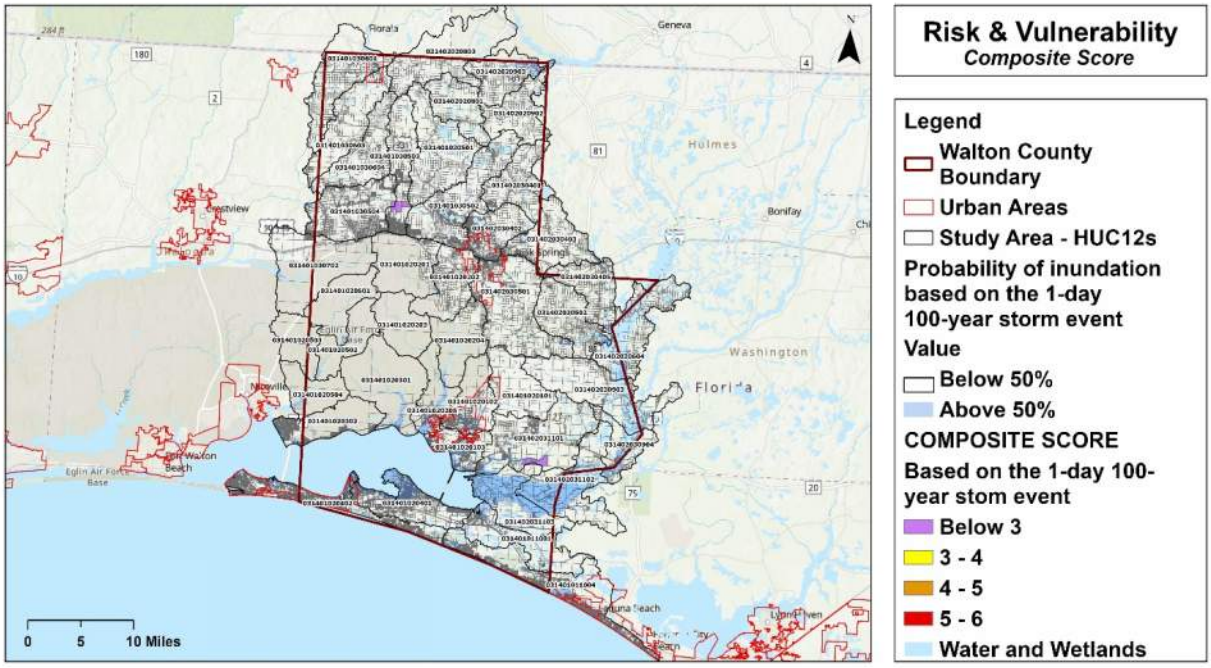

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020503. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evalu

ation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020503. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020503	12325.27
All of the 1-day 100-year storm event inundation	**74.27**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	18.36
B. Federal Land in 1-day 100-year inundation > 10 acres	55.91
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	0.00
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	0.00

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. Figure 40 indicates the results

from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

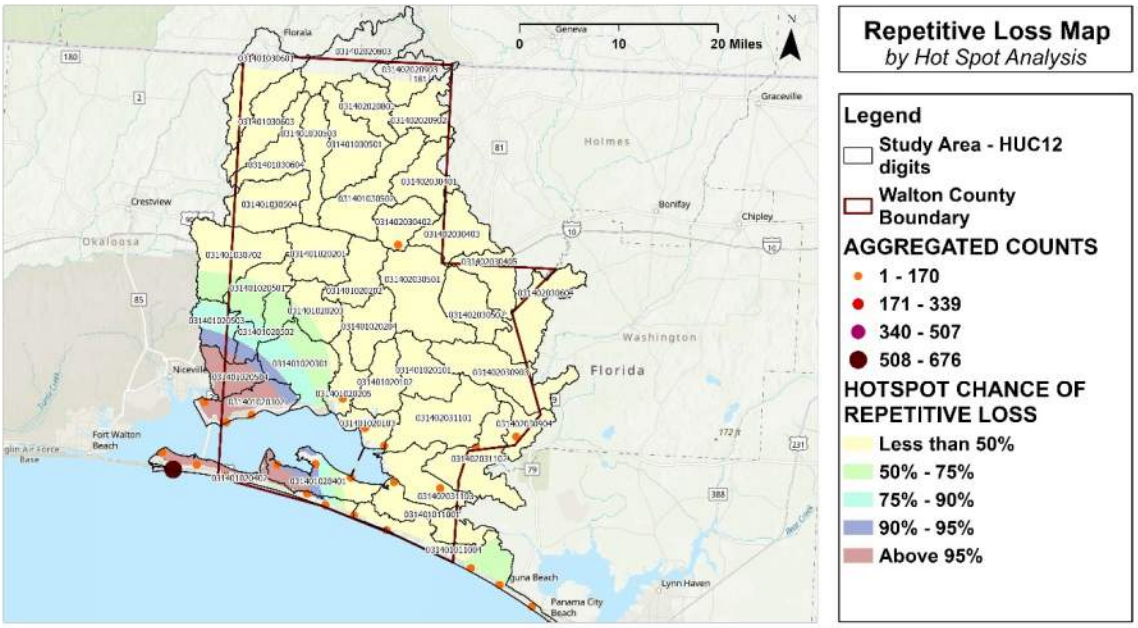

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5. Priority Projects

The entire HUC area is undeveloped and non-coastal. As a result, there are no critical facilities or other land uses that require priority intervention. The minor flooding and null composite score indicate that the HUC is not significantly affected by flooding, and there are no pressing priorities for interventions to address inundation impacts.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 sub-watershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds ((**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401020504) is highlighted among all the HUCs to help identifying its location. (Figure 3).

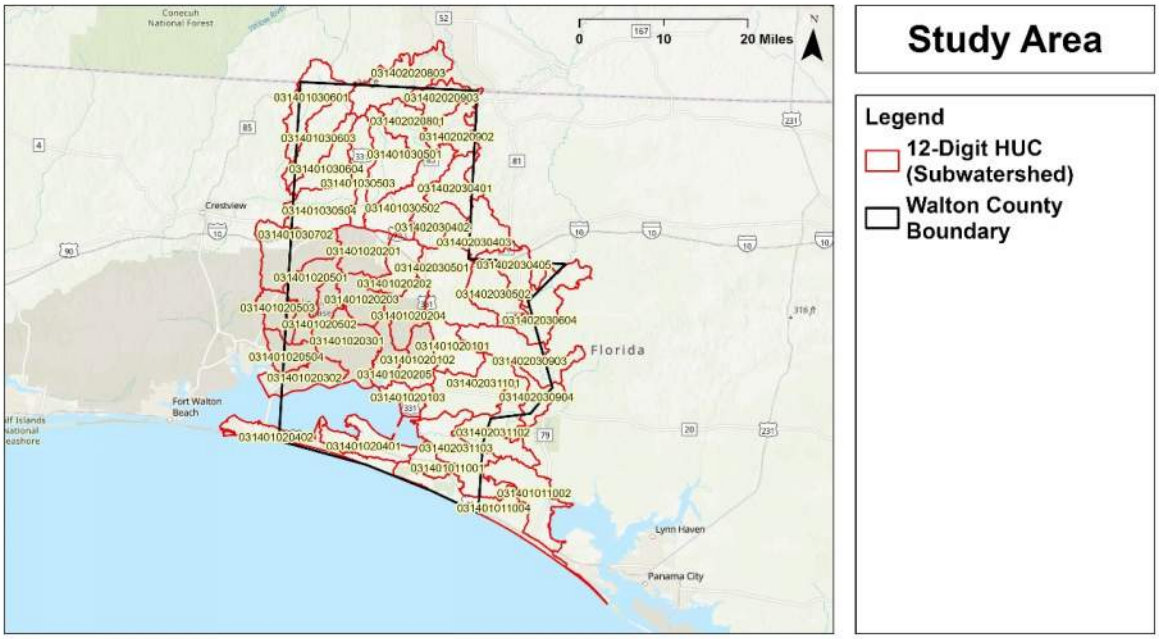

Figure 1. Walton County and all HUCs 12-digit sub-watershed, processed by FAU.

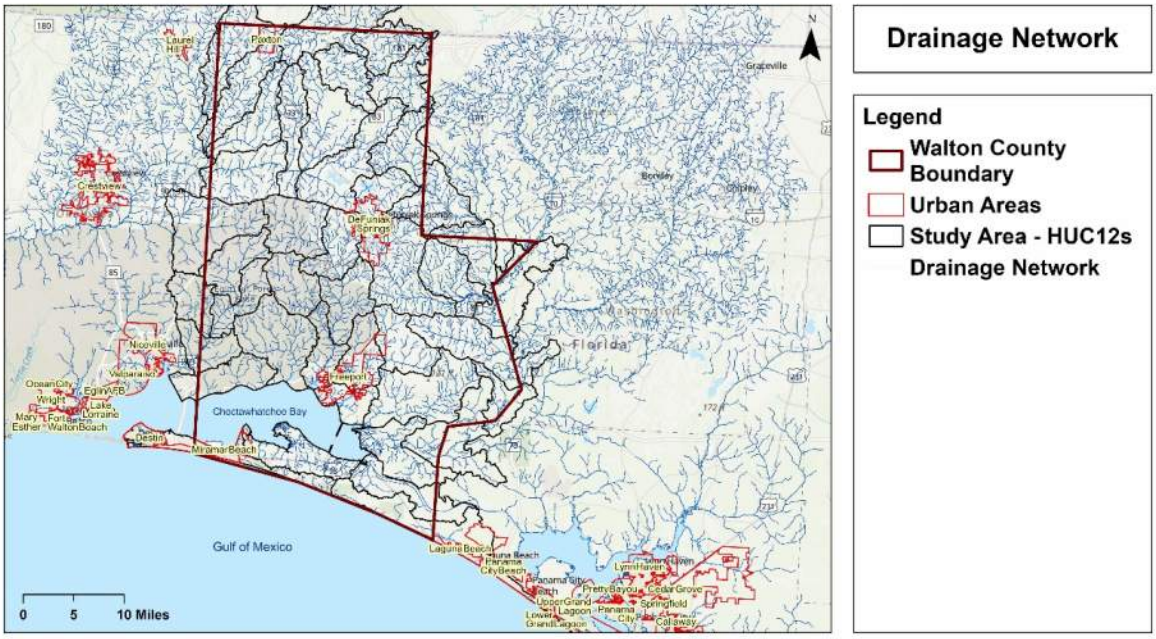

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

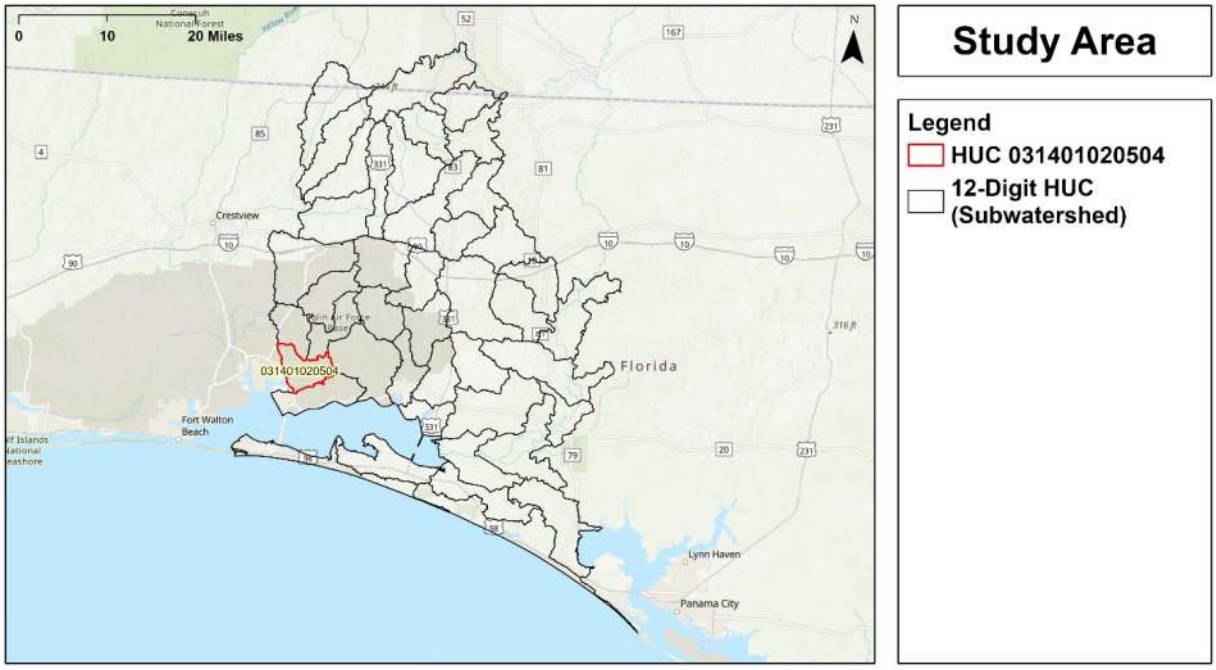

Figure 3. HUC 031401020504 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

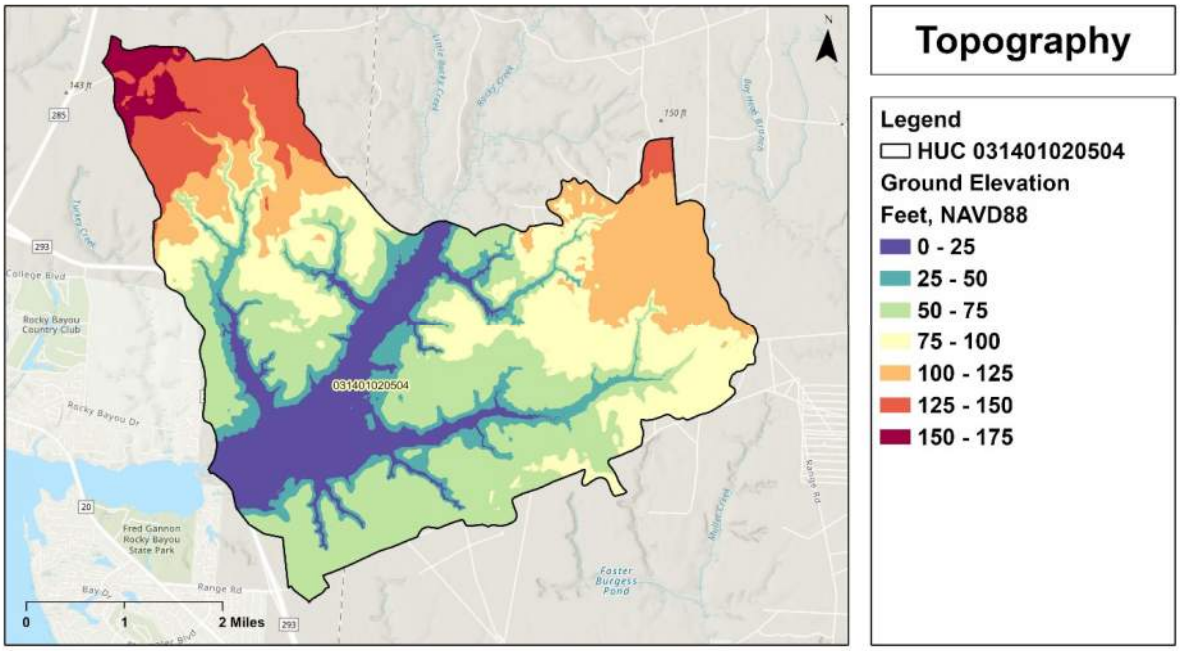

Figure 4. Topographic map of the HUC 031401020504 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401020504 sub-watershed is shown in Figure 5.

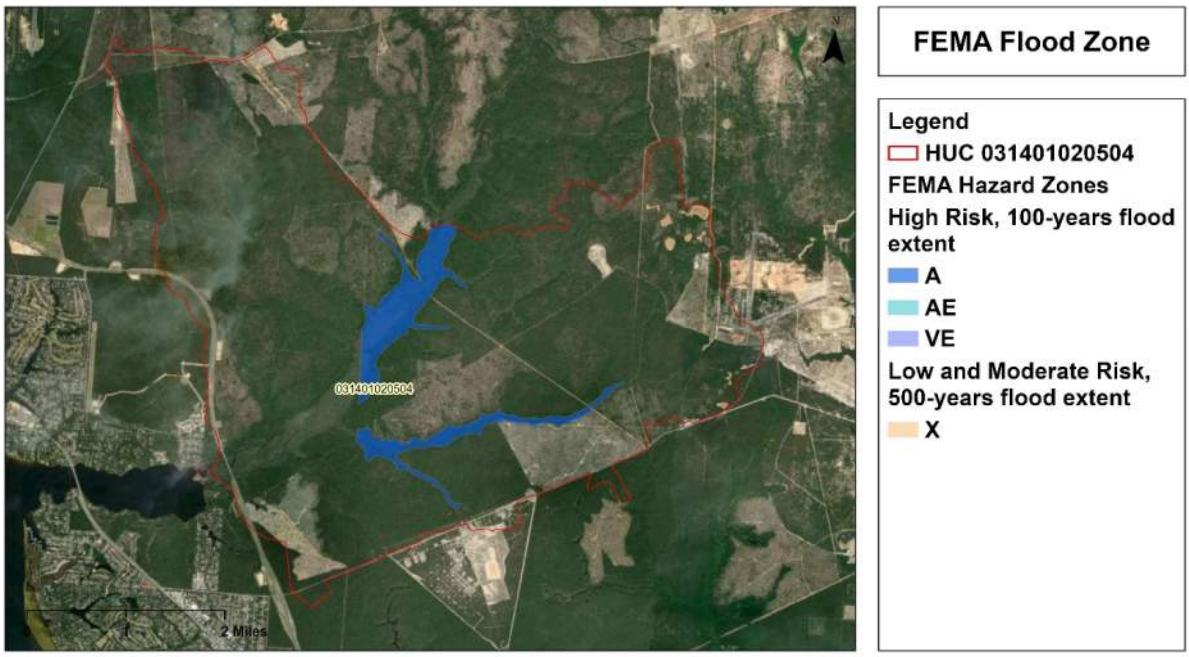

Figure 5. FEMA Flood Zone map (2020) for HUC 031401020504 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal

area, including the sub-watershed 031401020504 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

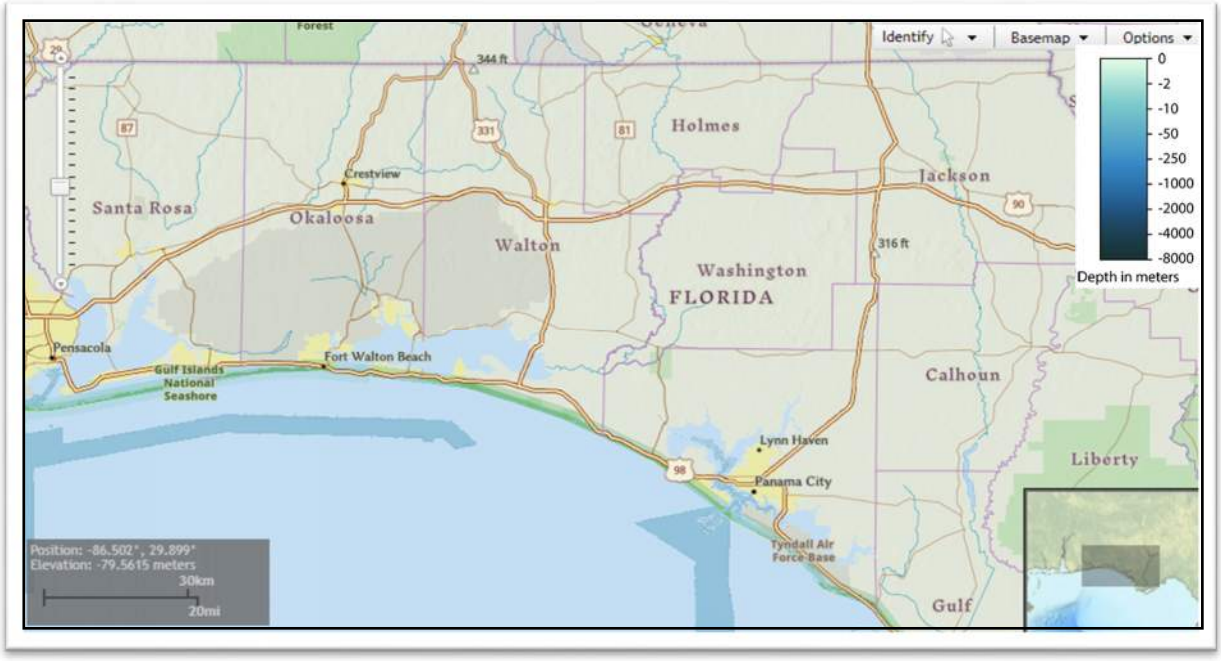

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

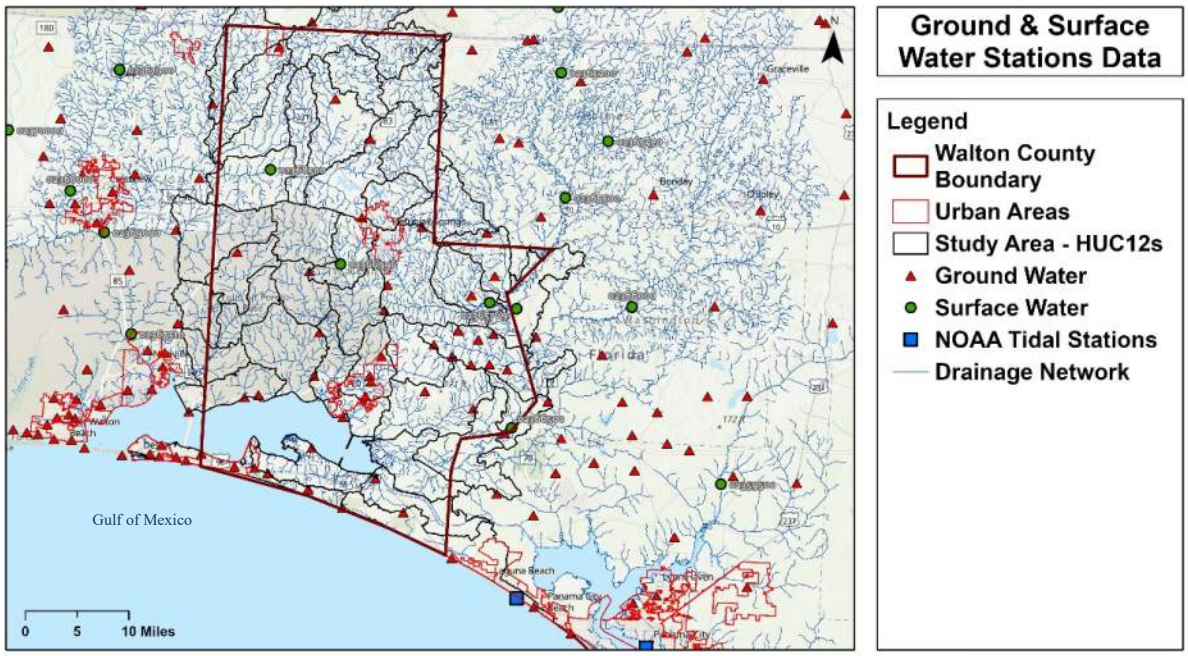

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401020504 connects to the ocean via Rocky Bayou. The major waterbodies within the basin include:

- Rocky Creek
- Smith Branch
- Long Creek
- Bee Branch
- Deep Head
- Hickory Branch

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02366996. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401020504, which is USGS 02366996 Alaqua Creek Near Pleasant Ridge, FL.

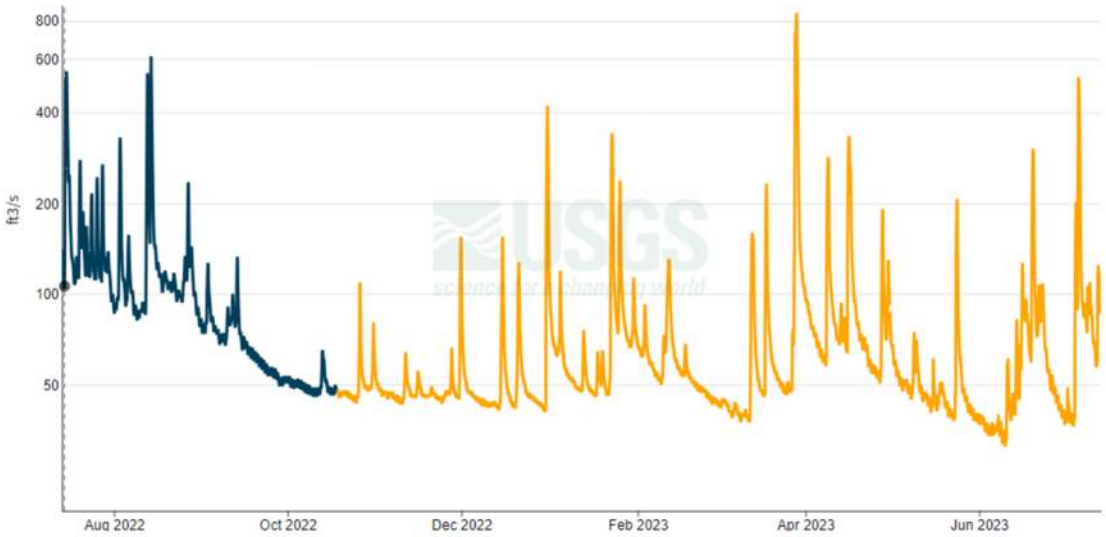

Figure 8. Average streamflow for Alaqua Creek Near Pleasant Ridge, FL (USGS 02366996 Surface-Water, June 2022 to July 2023.
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02366996/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to

process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401020504 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401020504 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

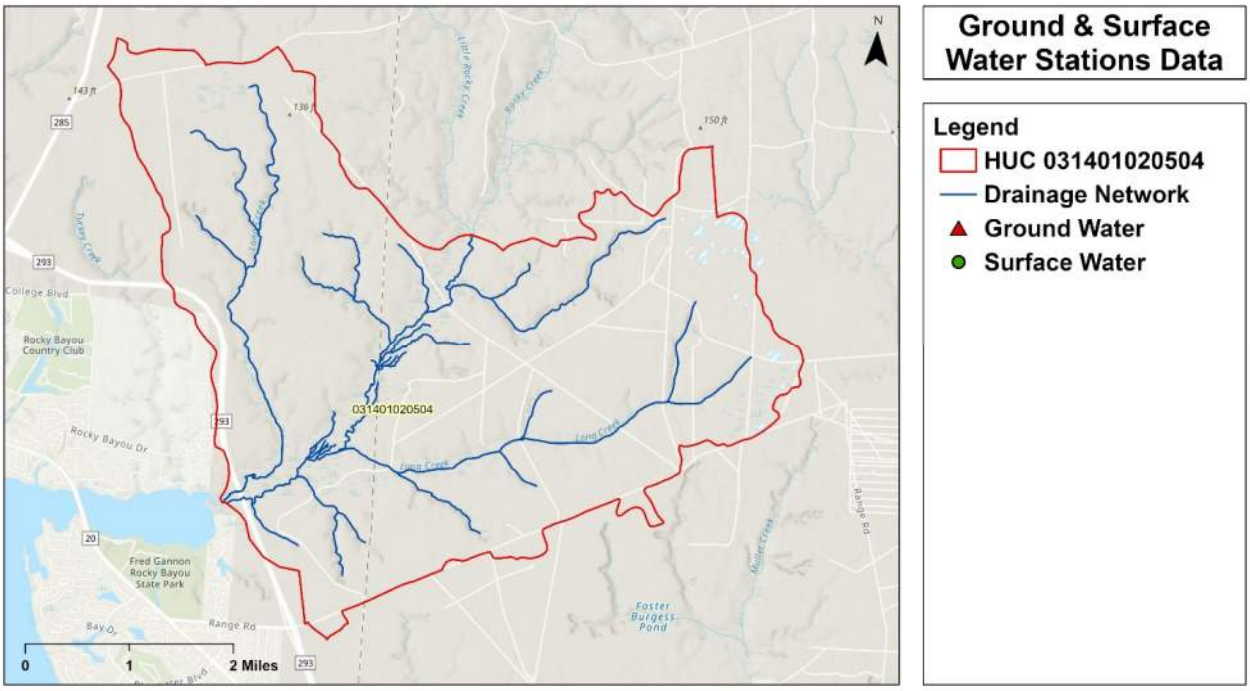

Figure 9. Ground and Surface Water Stations in the HUC 031401020504 sub-watershed, processed by FAU.

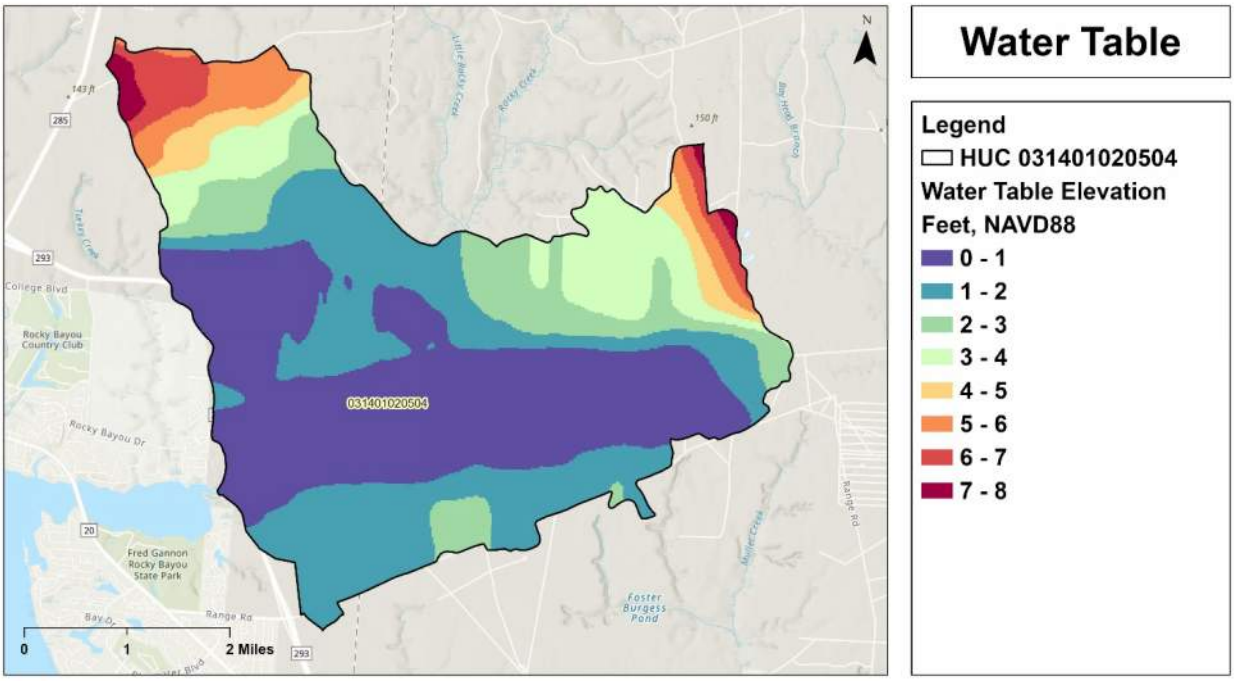

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401020504 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

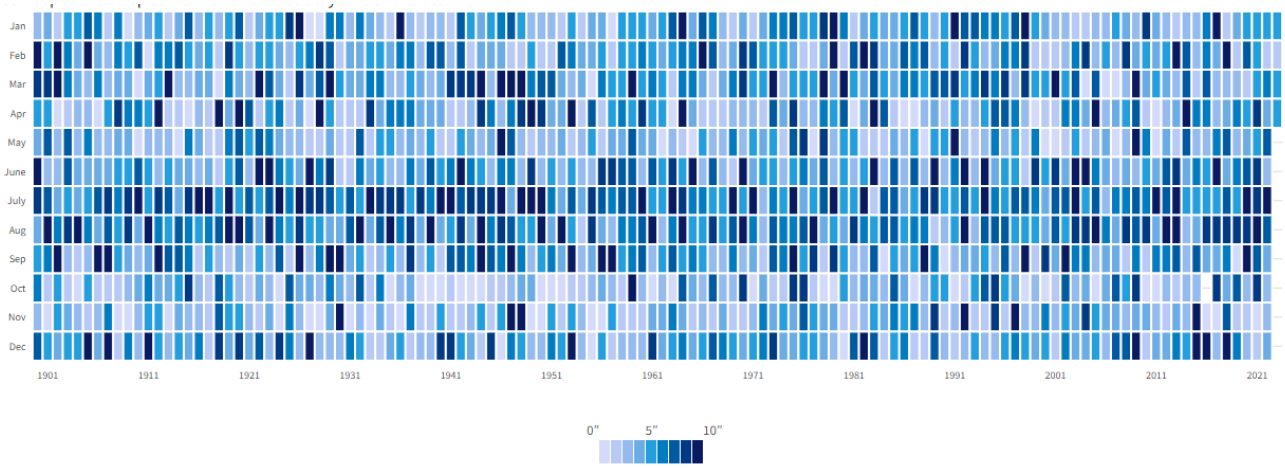

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

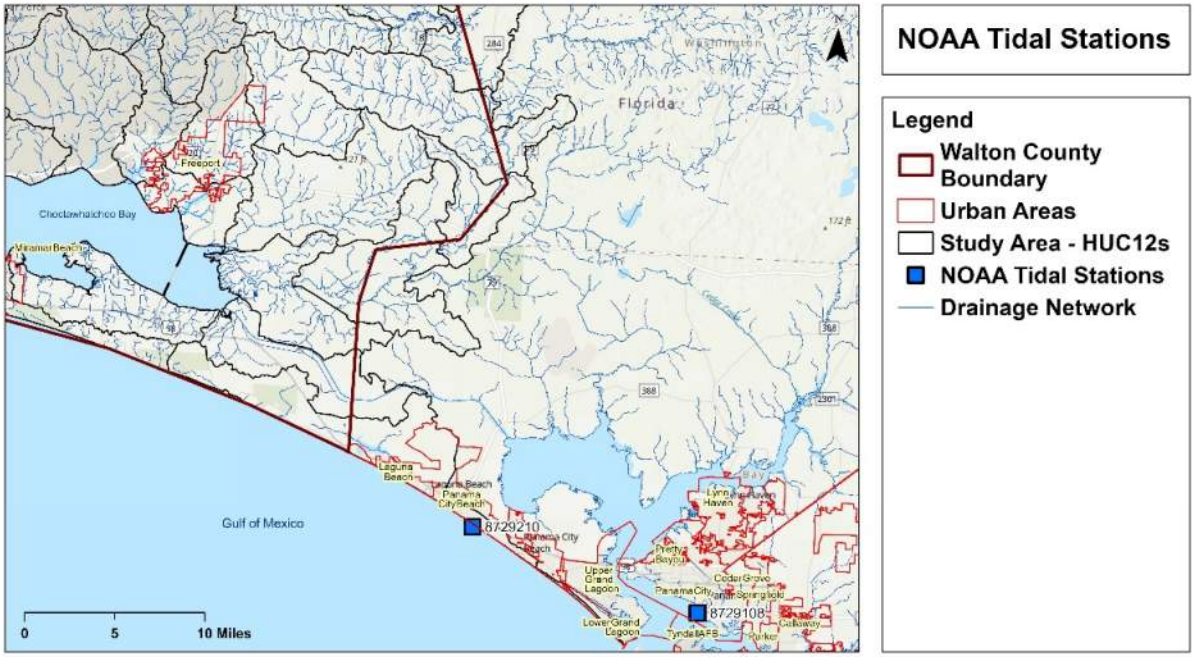

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

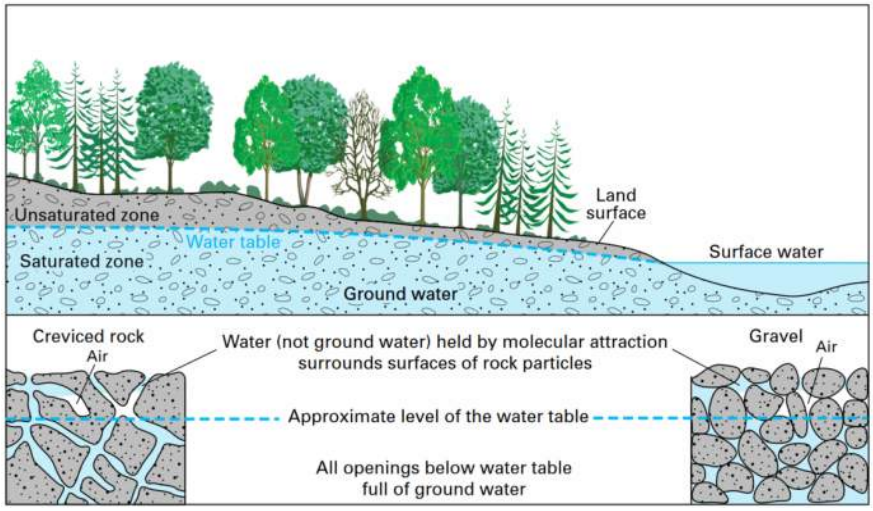

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

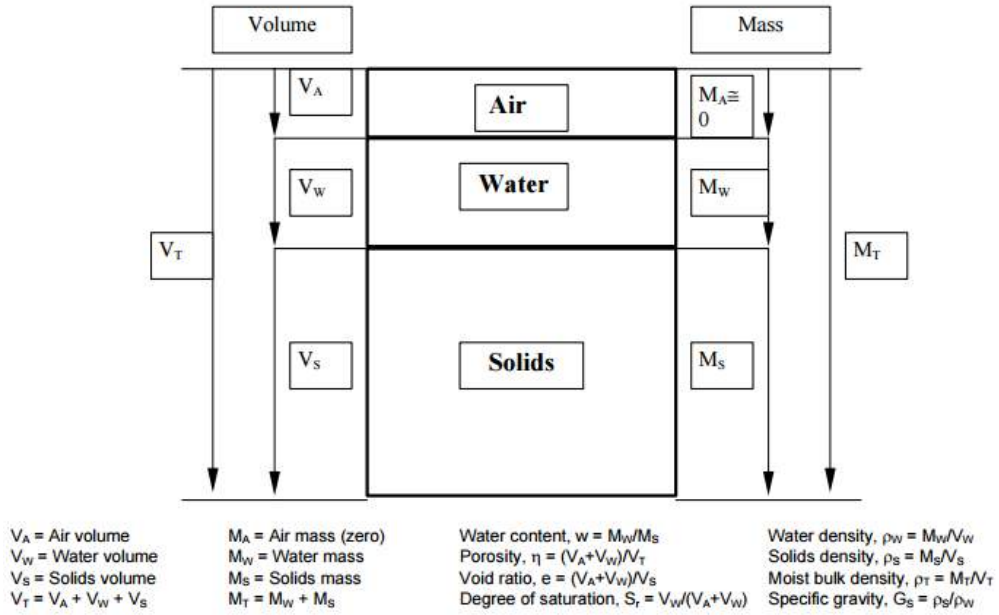

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

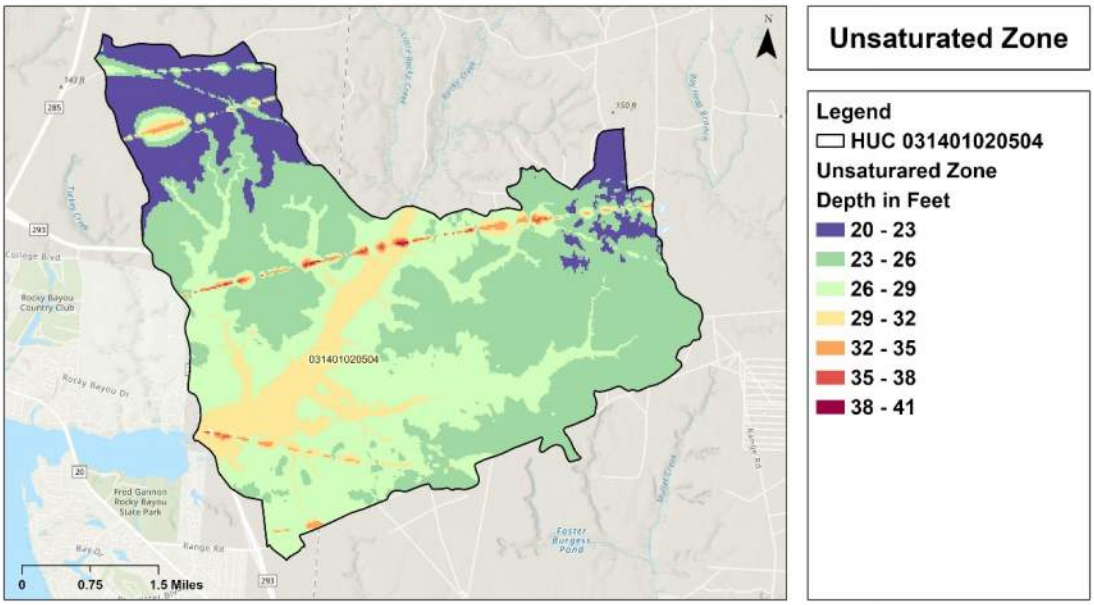

Figure 15. Unsaturated zone map for HUC 031401020504, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin demonstrates a moderate soil storage capacity, falling within the range of 20 to 32 feet of remaining capacity.

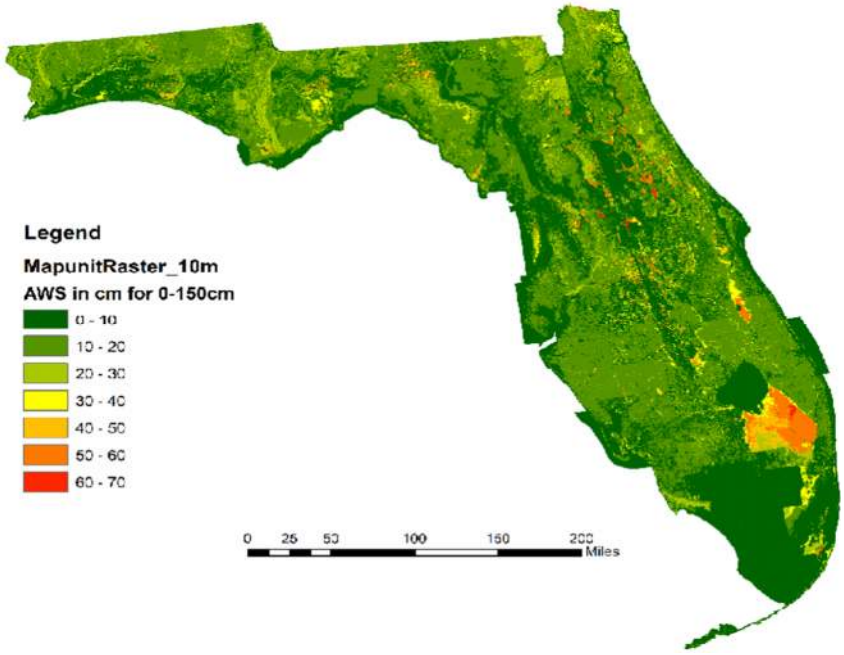

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

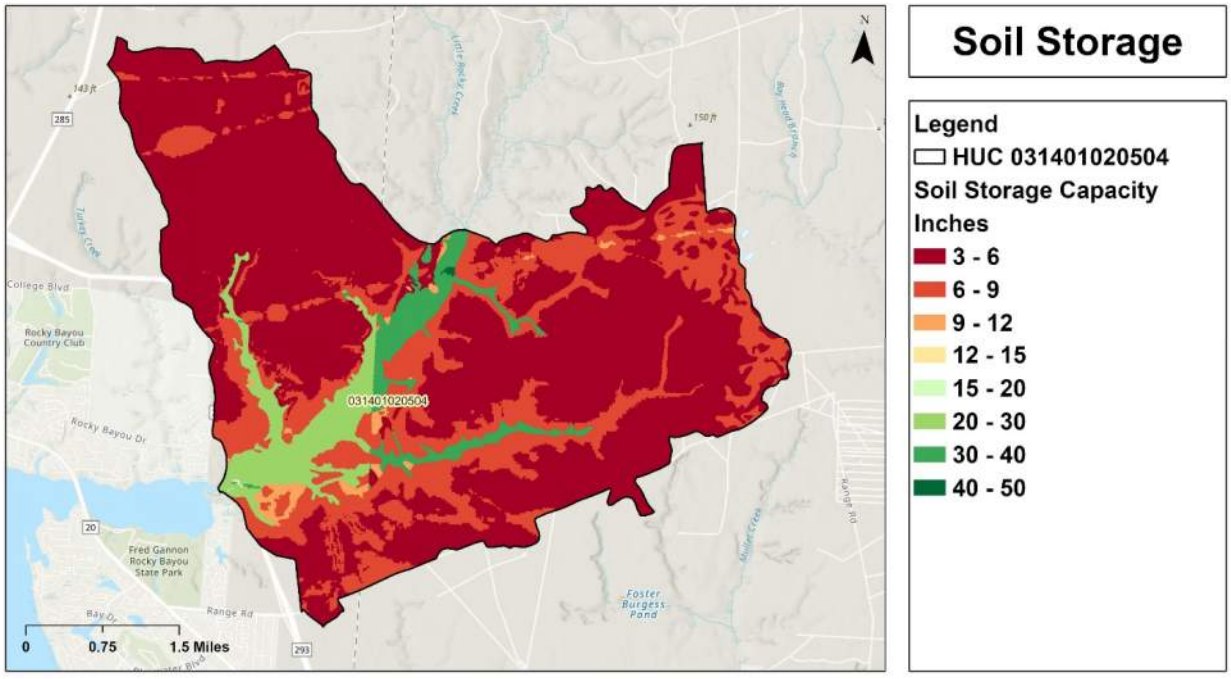

Figure 17. Water storage capacity of soil for the HUC 031401020504, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

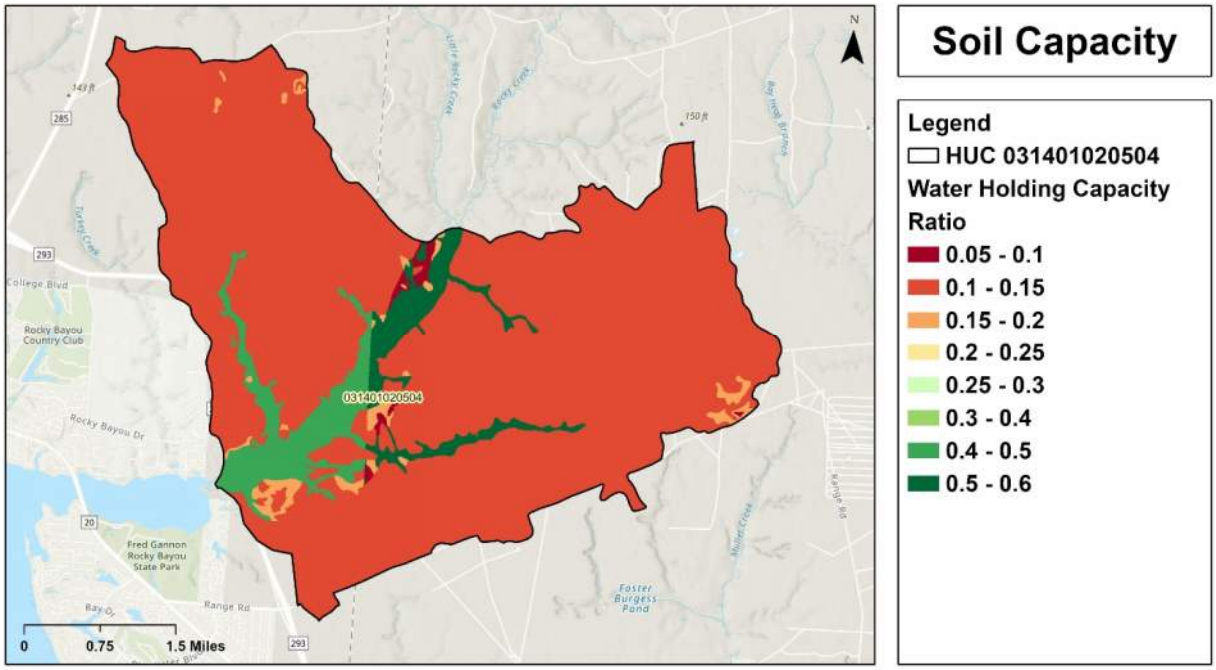

Figure 18. Water Holding Capacity (ratio) for the HUC 031401020504, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

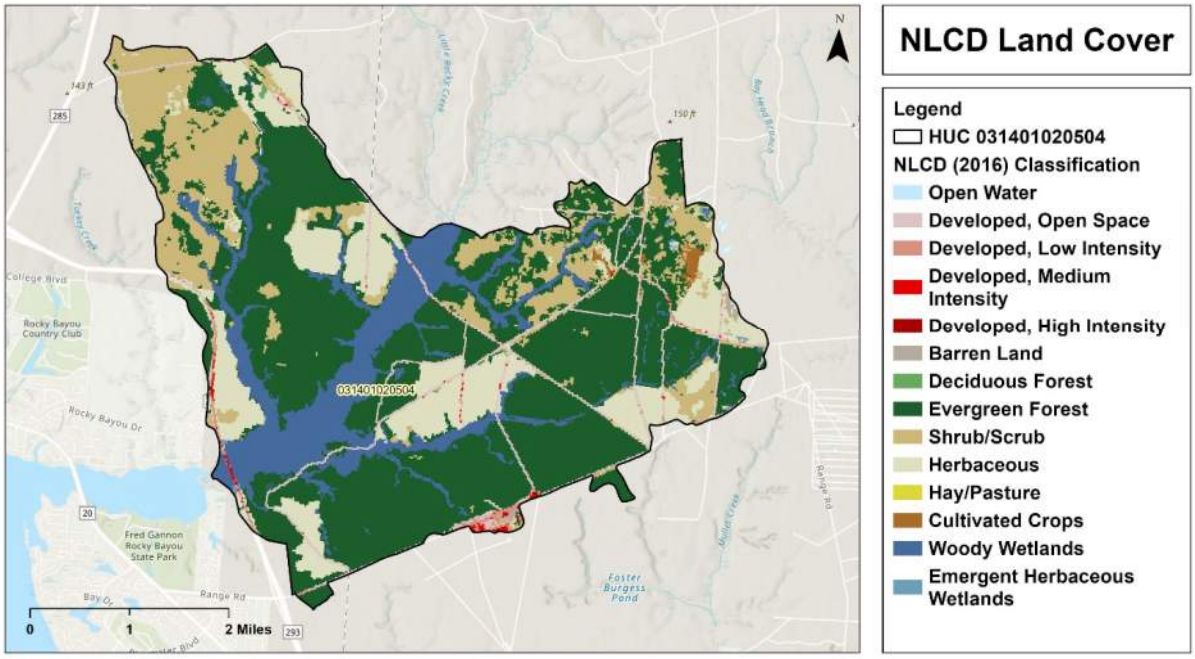

Figure 19. Land use in the HUC 031401020504 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

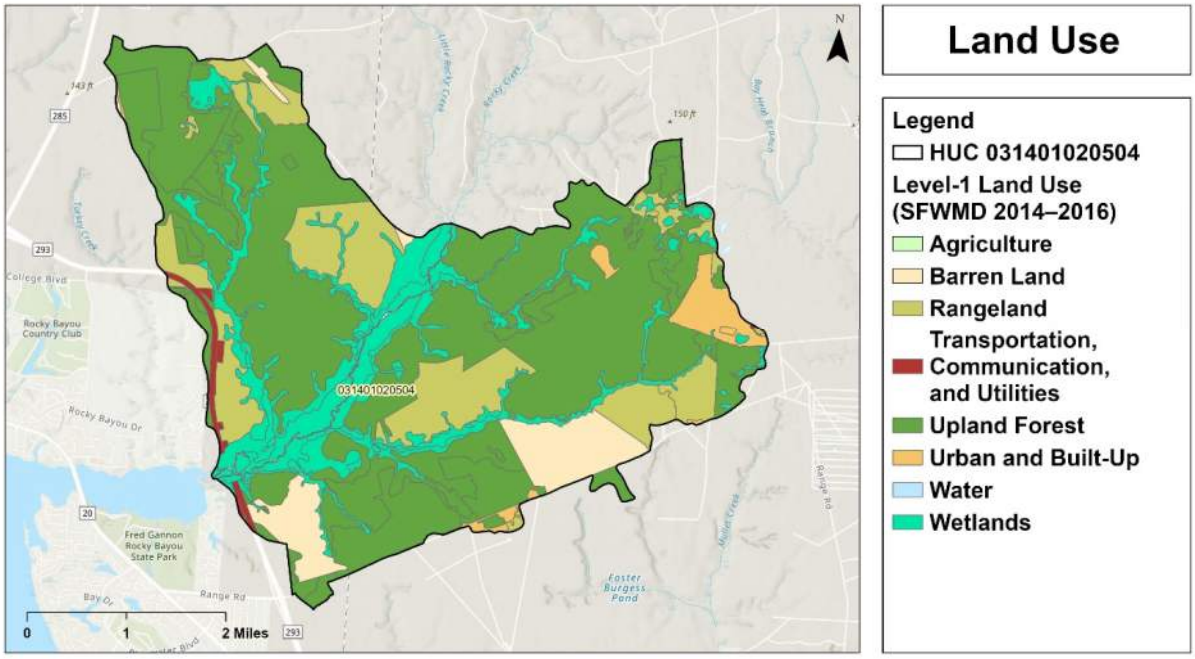

Figure 20. Land use in the HUC 031401020504 (2023 Florida Geographic Data Library (FGDL) database)) processed by FAU.

In the HUC 031401020504 sub-watershed, the predominant land cover is upland forest, accounting for 68.30% of the area. Rangeland comes in second at 9.72%, followed by wetlands at 8.51%. Developed land constitutes also a good portion, with 7.61% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401020504 sub-watershed (2023 Florida Geographic Data Library (FGDL) database)).

Level 1 Land Use Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	0.00	0.00%
Barren Land	887.38	3.74%
Rangeland	2306.56	9.72%
Transportation, Communication, and Utilities	465.05	1.96%
Upland Forest	16200.15	68.30%
Urban and Built-Up	1805.86	7.61%
Water	37.96	0.16%
Wetlands	2017.66	8.51%
Grand Total:	**23720.62**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

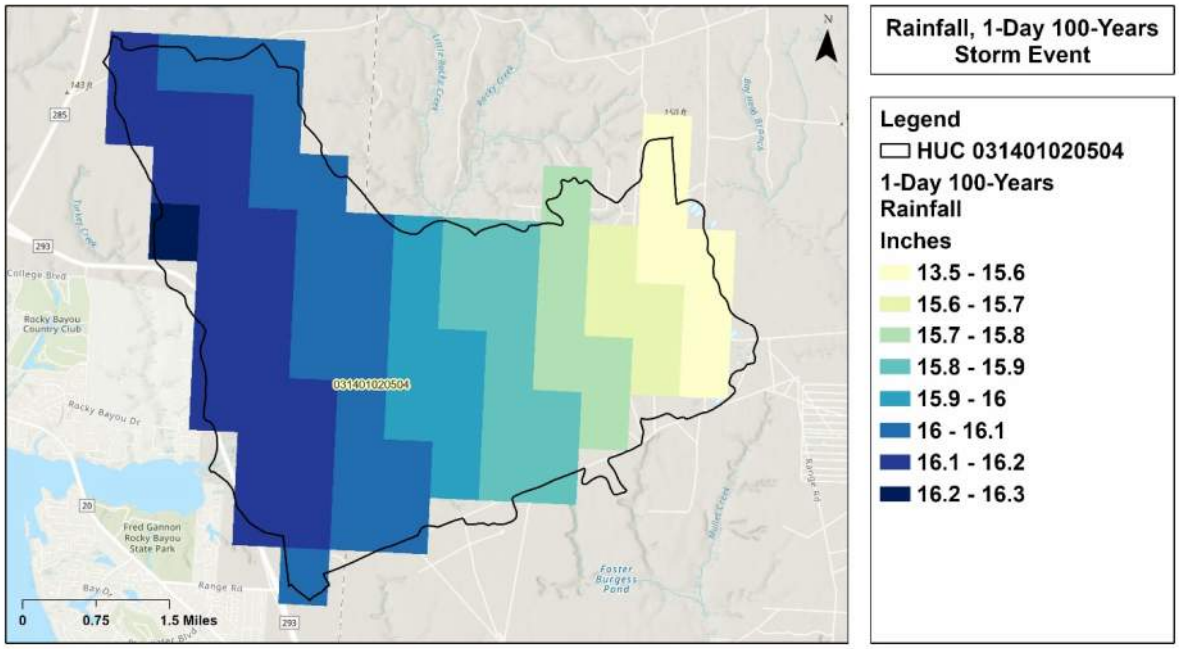

Figure 22. Rainfall distribution map across HUC 031401020504 sub-watershed, for 1-day 100-year storm event, processed by FAU.

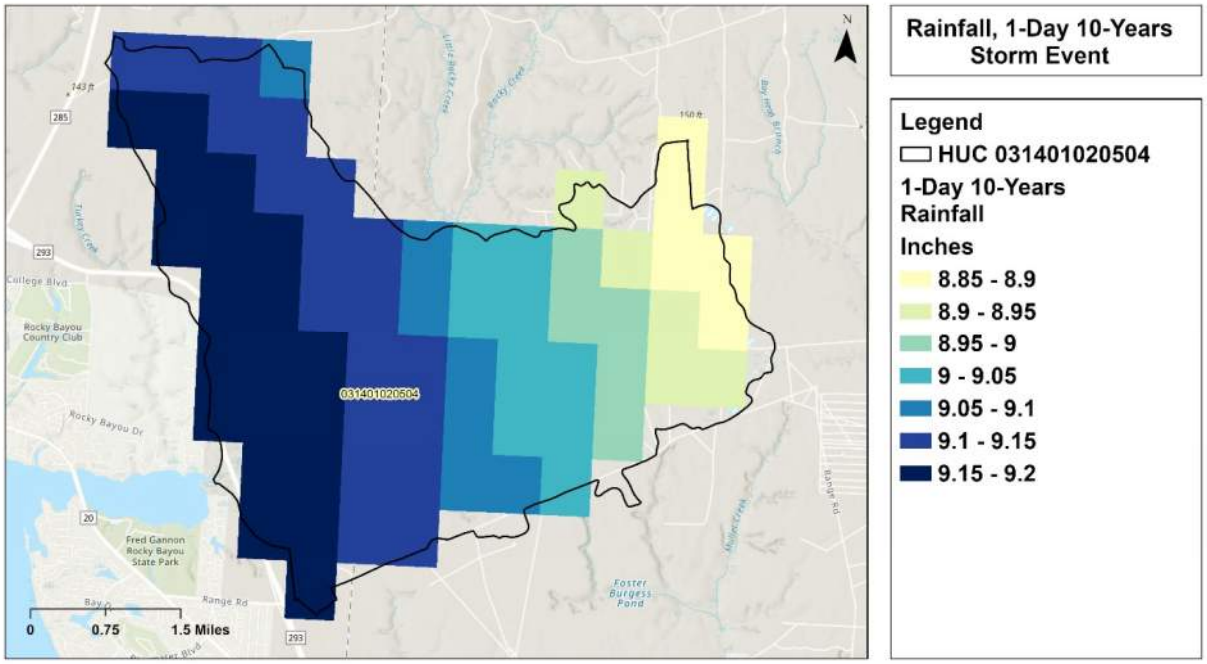

Figure 23. Rainfall distribution map across HUC 031401020504 sub-watershed, for 1-day 10-year storm event, processed by FAU.

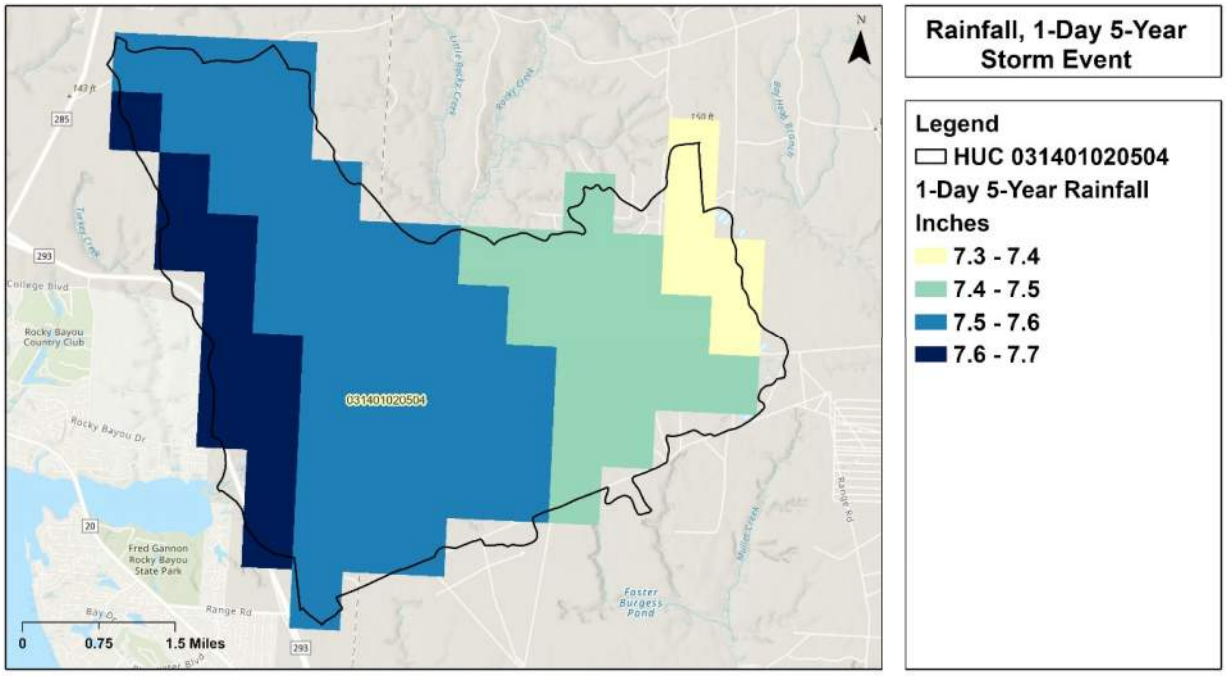

Figure 24. Rainfall distribution map across HUC 031401020504 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land

cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

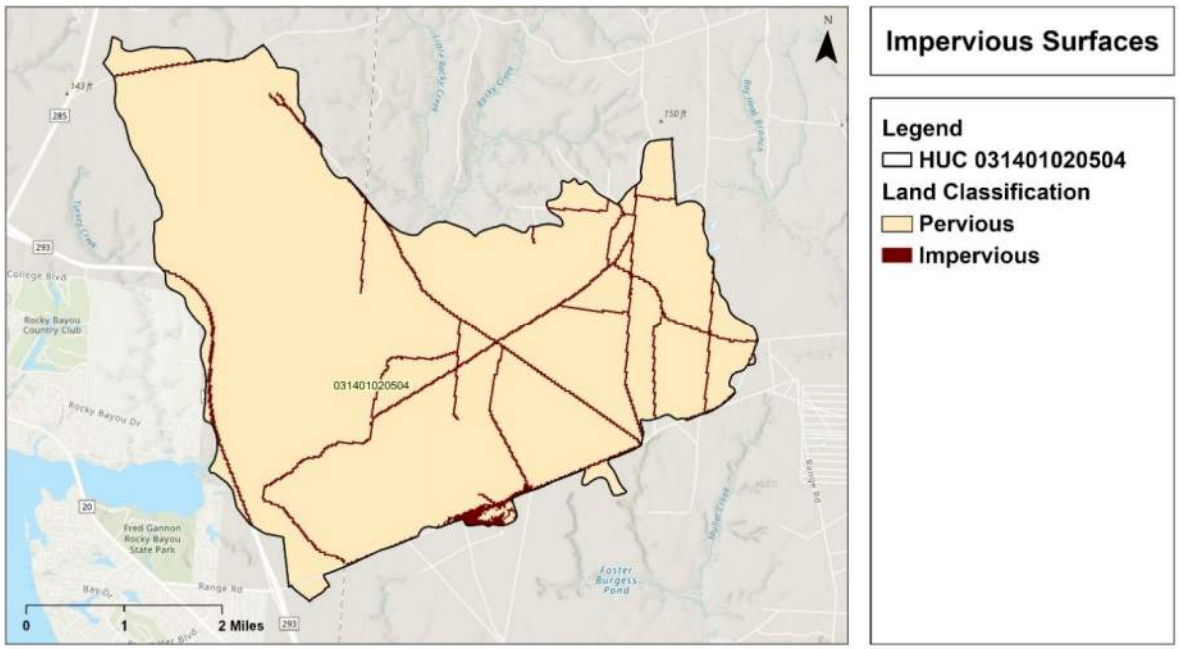

Figure 25. Impervious area map for the HUC 031401020504 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

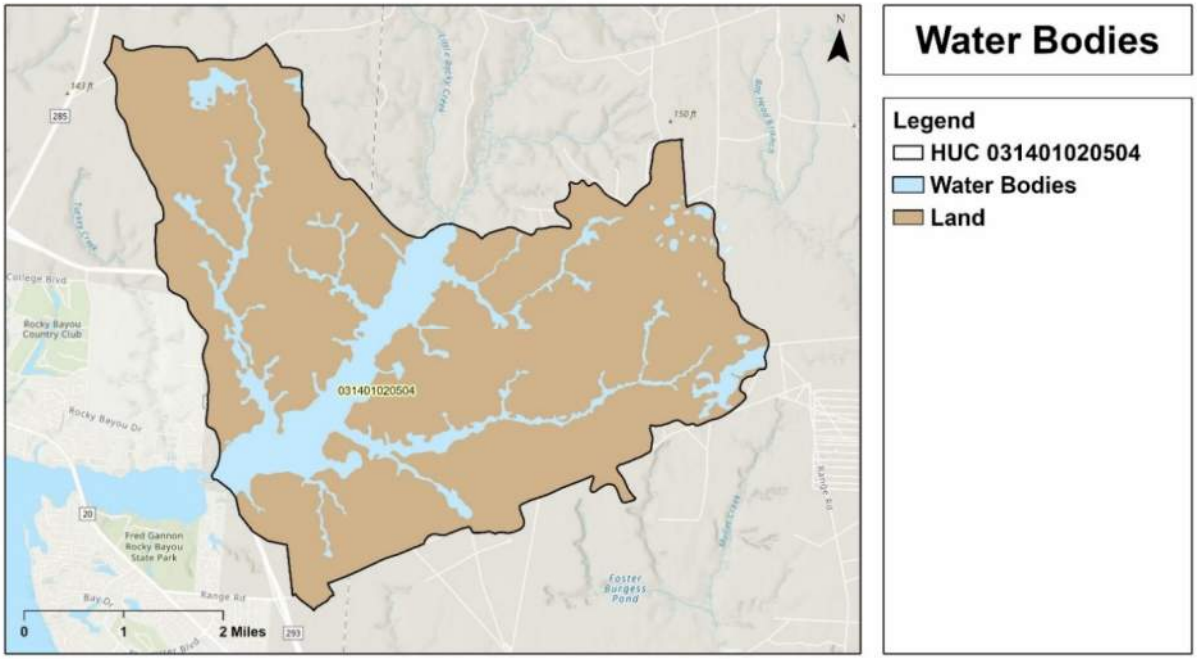

Figure 26. Water bodies map for the HUC 031401020504 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, , such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

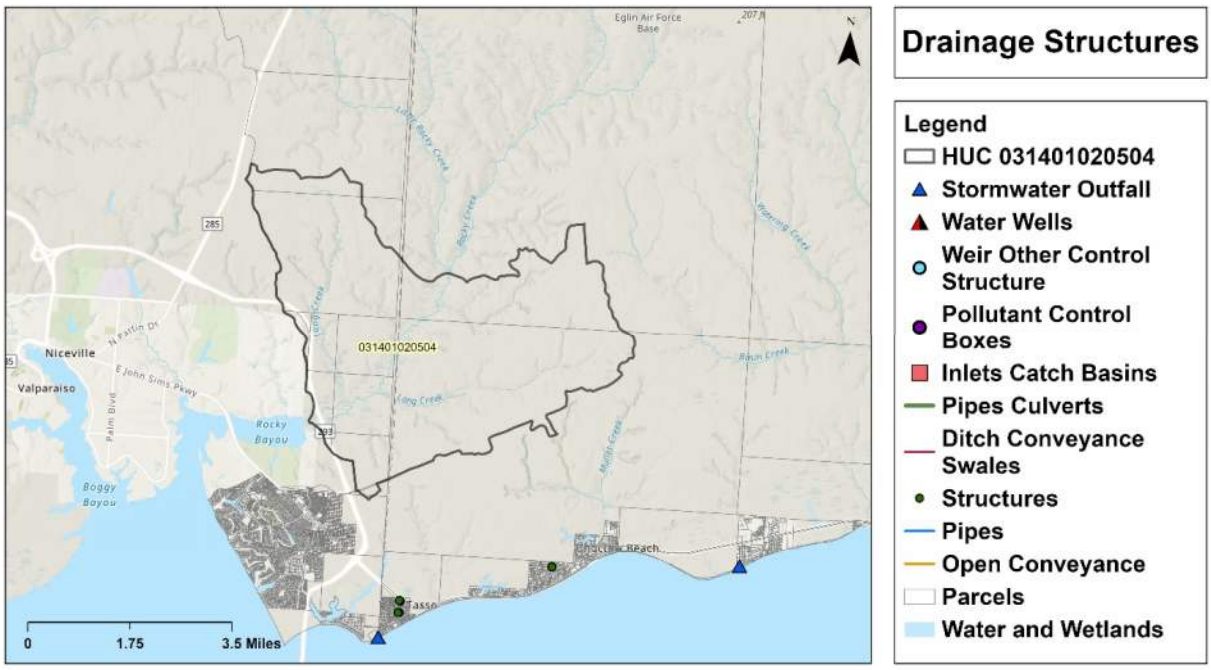

Figure 27. Stormwater Infrastructure for the HUC 031401020504. Processed by FAU.

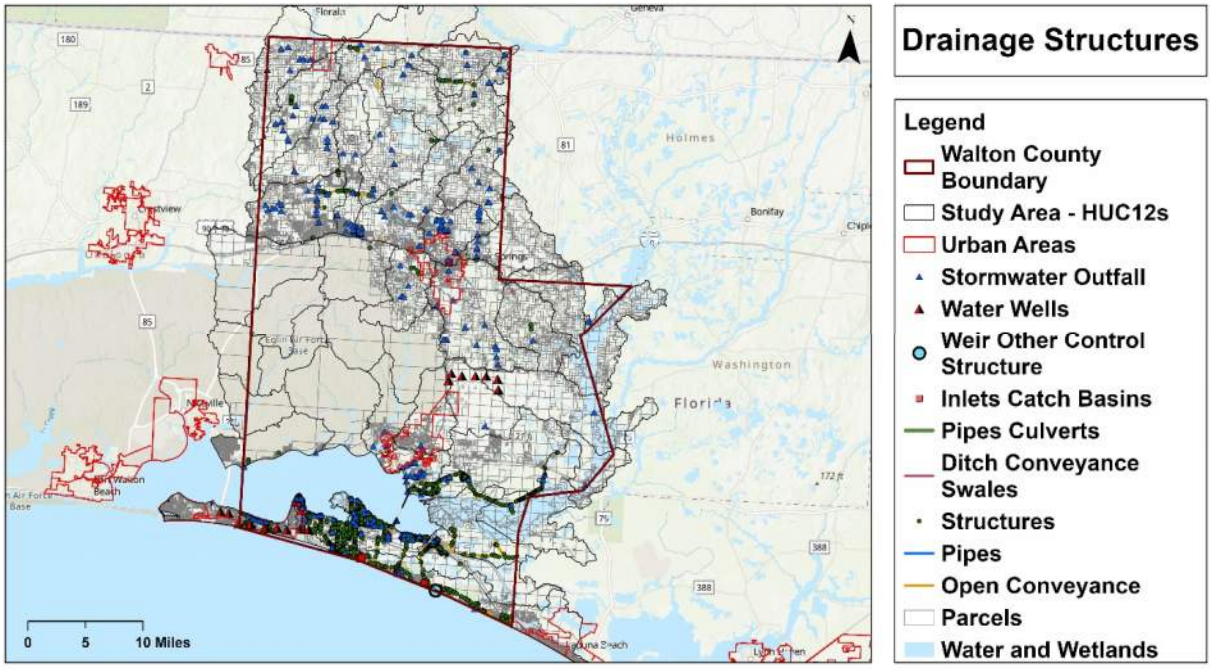

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401020504 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

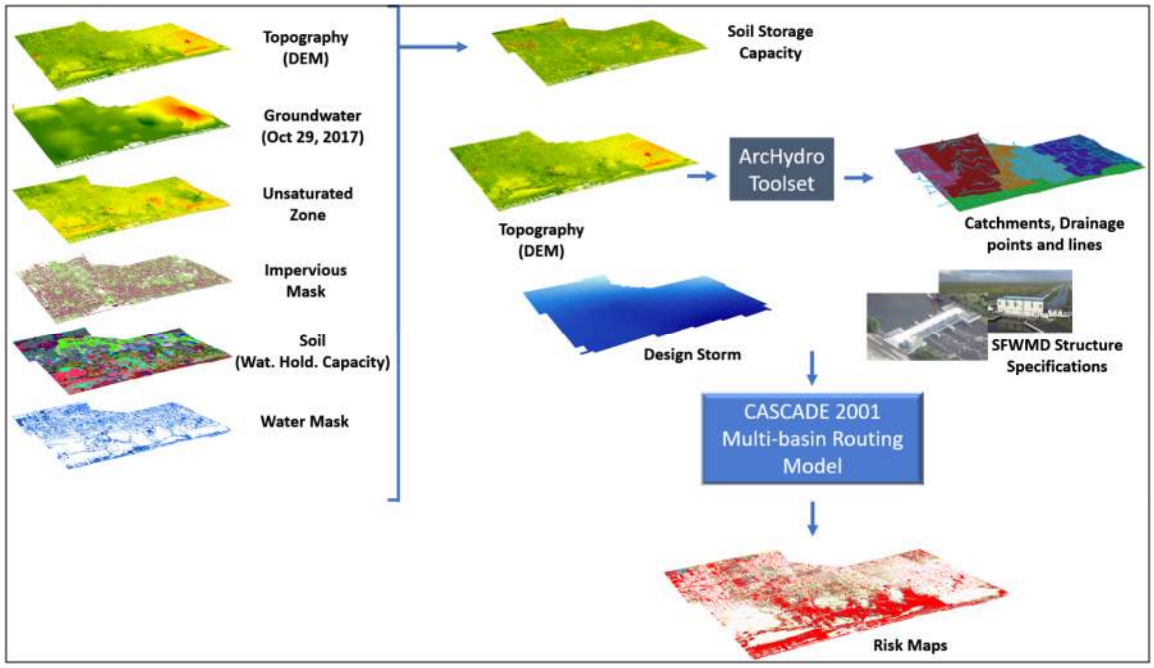

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

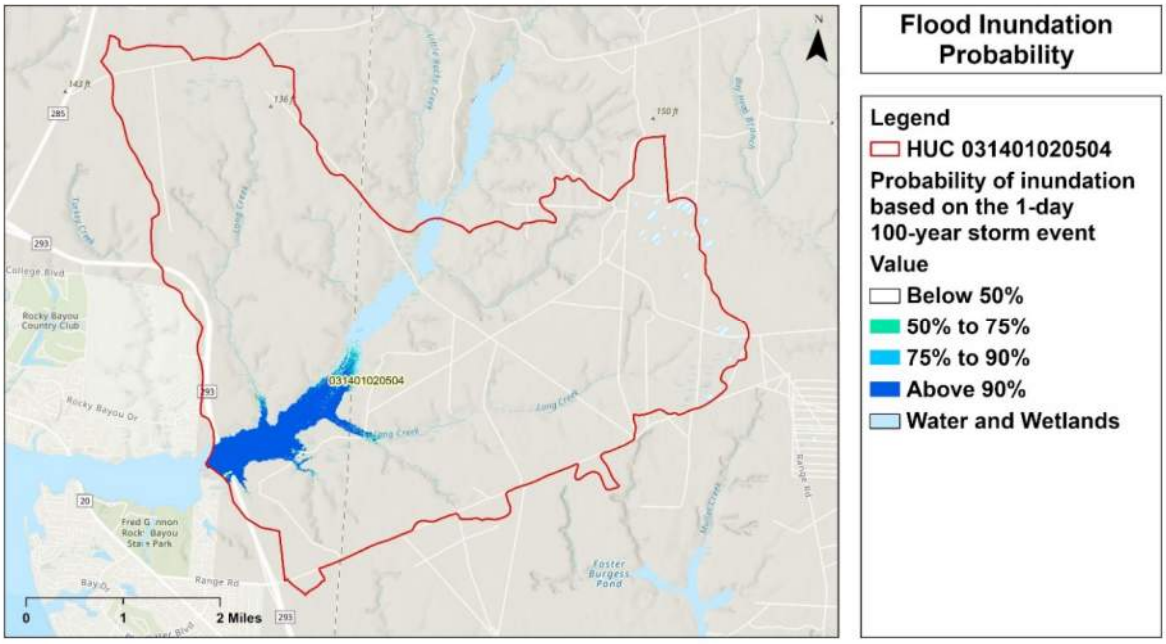

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401020504, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees

and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Future Challenges of Sea Level Rise and Climate Change

Global observations from satellites and long-term data collection have made it possible to document and analyze patterns in the Earth's climate. Scientific analysis of the impact of these changes has helped to improve the understanding of future flood hazard driving forces and long-term impacts on human activities and watershed master planning (http://www.research.noaa.gov/climate/t_observing.html). Examples of impacts are rising global average air and ocean temperatures, increased and earlier snow and ice melt, shorter subtropical rainy seasons, shifted seasons, sea level rise and greater variations in temperature and precipitation (IPCC, 2013; Freas et al., 2008; Marshall et al., 2004; Bloetscher et al., 2010). Marshall et al. (2004) specifically focused on the Florida peninsula to predict changes in rainfall and warmer temperatures but interspersed lower low temperatures due to the potential loss of wetlands.

Future changes in climate will add to the existing impacts, at a time when the population of the state is expected to nearly double by 2030. Additional research and high-resolution climate modeling for the Florida peninsula and local jurisdictions is needed to help guide long-term plans like WMPs. Rainfall appears to be decreasing and temperatures rising (see **Error! Reference source not found.**).

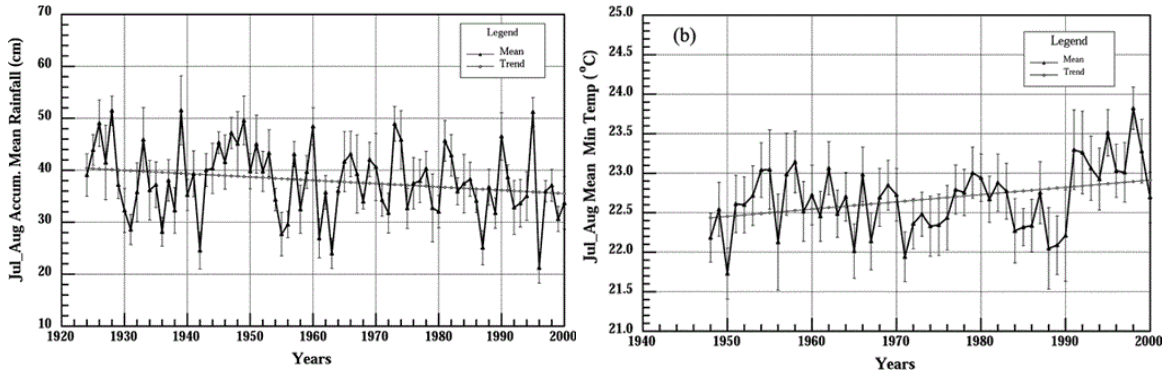

Figure 31. Change in average rainfall and change in average temp 1924 to 2000. Note the reversed trend, which means groundwater input variability is lessened. Source: Marshall et al., 2004.

Climate change is likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to the ocean, c) increasingly compromised stormwater drainage systems, and d) more frequent inundation of barrier islands and coastal areas.

NOAA and IPCC (2013) predictions suggest that by 2100, global temperatures will be on the order of 2-3°C (3-5°F) higher and sea levels will rise by up to 3 feet. Accompanying these drivers are potential changes in storm frequency and intensity, desertification, population migration, ocean acidification and coastal flooding (IPCC, 2007), exacerbated by the land cover and land use changes, which are substantially impacted by the fluxes, timing and quality of precipitation (Adrians et al., 2003; Scanlon et al., 2005; Marshall et al., 2004; Salmun and Molod, 2006), and leading to changes in the timing of peak flows and volumes (Richey and Costa-Cabral, 2006).

The results of these climatic changes are likely to: 1) threaten the integrity and availability of fresh water supplies and 2) increase the risk of flooding, not only in the low-lying coastal areas, but also in the interior flood plains. Other issues include a) saltwater intrusion, which may be intensified by sea level rise, b) prolonged droughts that will contribute to water supply shortages and wildfires, and c) heavier rains during the rainy season and higher hurricane storm surge, which may increase the risk due to flooding. More frequent and damaging floods are likely to become an ever-increasing problem as sea level continues to rise because of: a) increasing groundwater table elevations and surface water gage heights, b) reduced groundwater seepage through the aquifer to

the ocean, c) increasingly An outcome of these climatic patterns is that during the past 140 years, an increase in sea levels has been observed (Bloetscher, 2012), a worrying pattern since sea level rise is a permanent phenomenon, that can be catastrophic to low lying areas in the long-term. The question is how much and how soon? Various studies (Bindoff et al., 2007; Domingues et al., 2008; Edwards, 2007; Gregory, 2008; Vermeer and Rahmstorf, 2009; Jevrejeva, Moore and Grinsted, 2010; Bloetscher, 2010, 2011; IPCC, 2007; Heimlich et al., 2009) indicate large uncertainty in projections of sea level rise by 2100. Gregory et al. (2012) note that during the last two decades, the global rate of sea level rise has been larger than the 20th-century time-mean, and Church et al. (2011) suggested that the cause was increased rates of thermal expansion, glacier mass loss, and ice discharge from icesheets. Gregory et al. (2012) suggested that there may also be increasing contributions to global sea level rise from the effects of groundwater depletion, reservoir impoundment, and loss of storage capacity in surface waters due to siltation. Measurements of Florida's east coast (Maul, 2008) show an average rate of sea level rise of 2.27 ± 0.04 mm per year from 1915 to 1992 based on tide gauge readings. Analyzing the tidal gauge readings for Florida shows that:

1. Florida average sea level rise is 2.10 ± 0.49 mm/yr
2. All but one location is within the 95% confidence limit range (the exception is Panama City where there is evidence of submergence and other land-based issues)
3. None of the Florida sea level rise rates differ statistically
4. Average global sea level rise for 1920-2000 was 2.0 mm/yr – within 95% confidence limit for Florida locations

From 1929 to 1992, over eight inches of sea, with another 6 inches added since 1992, which is already having significant impacts on coastal communities where population growth has increased the need for improved flood management strategies (Bloetscher, 2008; Parkinson, 2010; Zhang et al., 2011, 2011a; NFIP, 2011; Schmidt et al., 2011; Warner et al., 2012).

As a result, the SFRCCC (2015) adopted USACE's methodology to derive scenarios of sea level change intermediate to high rates of sea level rise for years 2030 (3" to 7") and 2060 (9" to 24") as the consensus projection to guide future planning. The path keeps increasing – now 14 inches since 1929 (**Error! Reference source not found.**) caused by thermal expansion of the ocean and melting ice caps (Jevrejeva et al., 2010; Vermeer and Rahmstorf, 2009). Sea level rise is a major concern in Florida, including Walton County, since the majority of the state's population live on the coast, involving most major commercial, residential, and economic enterprises. **Error! Reference source not found.** demonstrate the estimated sea level change for Panama City, considering the predictions of NOAA 2017. For NOAA high scenario SLR change scenario, the estimated level change is higher than 8 ft., while for the intermediate and low scenarios are about 3.9 feet and 1.7 feet respectively.

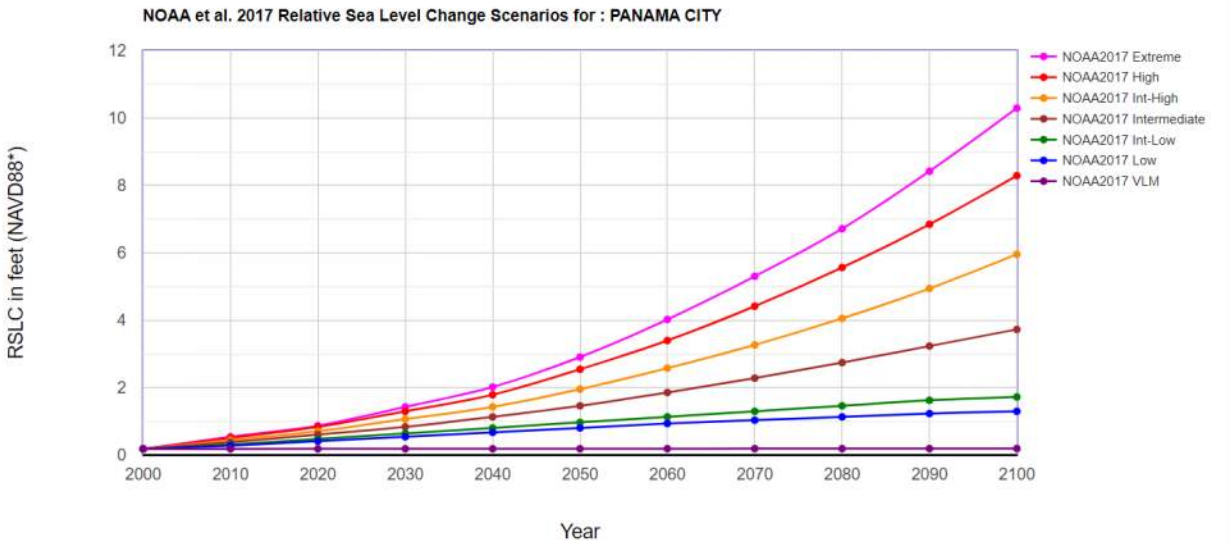

Figure 32. Relative Sea Level Change Scenarios for gauge 8729108, Panama City, FL. Source: NOAA 2017 (https://cwbi-app.sec.usace.army.mil/rccslc/slcc_calc.html).

NOAA (2017) outlines five scenarios for sea level rise. The NFIP proposes the use of the intermediate high projection, which is 1.2 meters or 4 ft globally from current sea level elevations (**Error! Reference source not found.**).

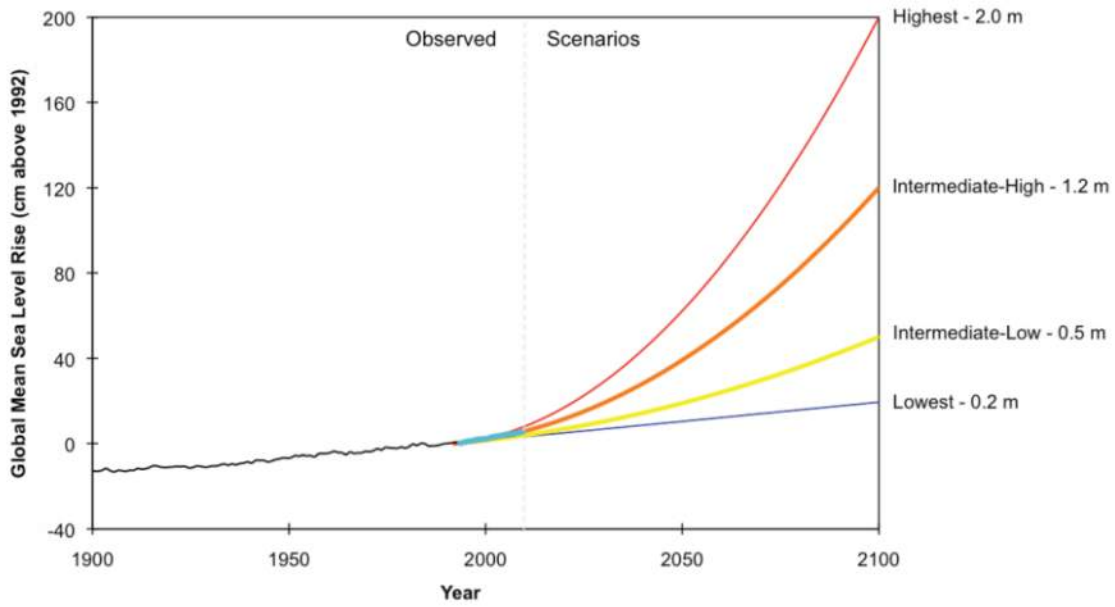

Figure 33. Graphic of global sea level rise projections from NOAA (2017). Source:https://tidesandcurrents.noaa.gov/publications/techrpt83_Global_and_Regional_SLR_Scenarios_for_the_US_final.pdf

As sea level rises, access to roads, bridges, rail, and transit could be at risk of flooding, causing the effects of sea level rise to spread indirectly throughout the entire transportation network, affecting the overall system performance. For example, the flooding of a critical road or facility access can cause a shifting of traffic flow causing congested conditions in other roadways that are not actually flooded. Since the roadway network would be unable to carry the traffic demand, the system would experience operational failure; as a result, causing travel times and delays. Moreover, the inundation of a critical access could cause transportation connectivity problems to essential infrastructure like ports or airports. Transportation infrastructure relies on the effectiveness of flood control and stormwater drainage systems for the transportation corridors. Road integrity relies on adequate drainage. The increased risk of severe flooding in Florida's low-lying terrain can adversely affect transportation infrastructure along the coastline; roads can be inundated, and roadway beds can be damaged. Sea level rise will cause increased water table levels (FDOT, 2012), as regional water tables cannot exist naturally below mean high tide (2 feet in Florida). Adding 3 feet of sea level rise on top of groundwater would compound the risk of flooding in low-lying areas. Road bases below 5 feet NVGD would become saturated under this scenario, likely causing premature base failure. As soil storage capacity is diminished due to rising groundwater elevations associated with sea level rise, the potential for more frequently flooded roadways would likely damage pavements (FDOT, 2012). Hence sea level rise must be accounted for in WMPs in coastal areas. To allow flexibility in the analysis due to the range of increases within the different time periods, an approach that uses incremental increases of 1, 2, and 3 feet of sea level rise is suggested for modeling. The increments can work as threshold values in planning considerations in terms of allowing planners the ability to know ahead of time where the next set of vulnerable areas will be, to allow for a proactive response approach that can be matched to the observed future rates. Sea level rise is a major concern since nearly half the US population lives within 50 miles of the coast, involving most major commercial, residential, and economic enterprises. The effects of 5 ft sea level rise, King tide, and 1-day 100-yr storm event are shown in **Error! Reference source not found.**.

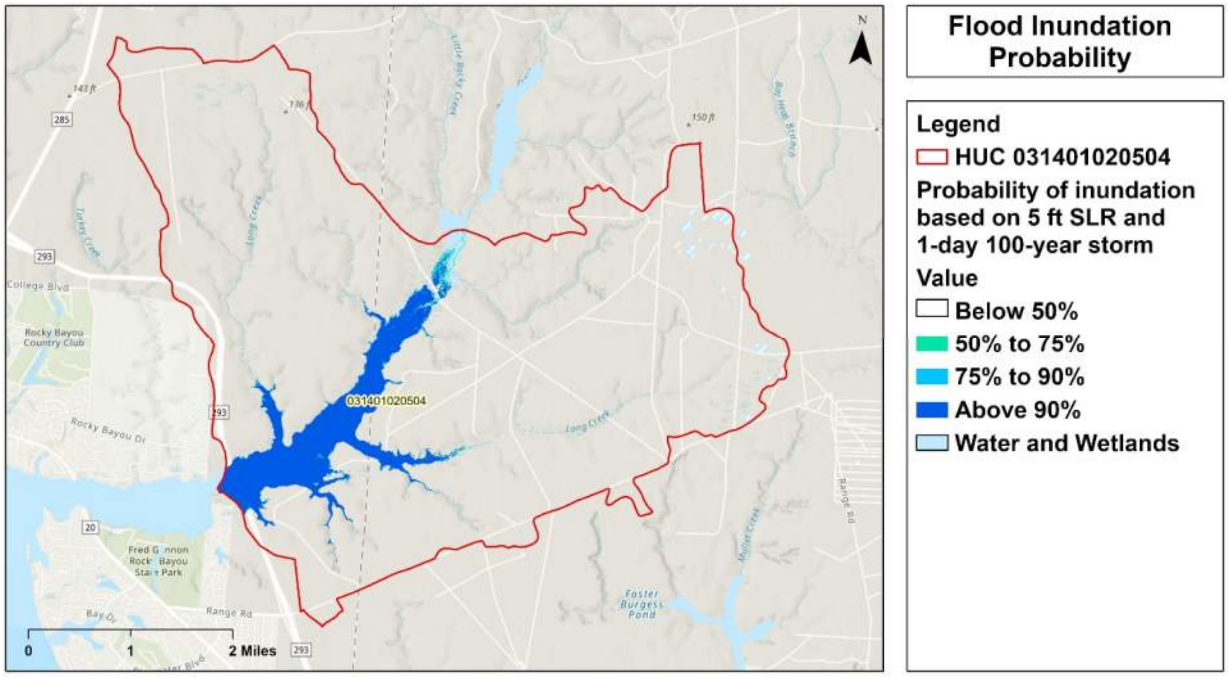

Figure 34. Flood Inundation Probability for a Sea level rise of 5 ft + 1-day 100-year storm event for HUC 031401020504 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations.
Dark blue is area under 5 ft NAVD88 and potentially inundated at the 99th percentile tidal conditions. Processed by FAU.

2.4 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. **3-day 25-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 35)
2. **1-day 100-year storm event**. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 36)
3. **1-day 10-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 37)
4. **1-day 5-year storm event.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 38)
5. **Sea level rise of 1 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 39)

6. **Sea level rise of 1 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations storm (Figure 40)
7. **Sea level rise of 1 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 41)
8. **Sea level rise of 1 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 1 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 42)
9. **Sea level rise of 2 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 43)
10. **Sea level rise of 2 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 44)
11. **Sea level rise of 2 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 45)
12. **Sea level rise of 2 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 2 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 46)
13. **Sea level rise of 3 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 47)
14. **Sea level rise of 3 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 48)
15. **Sea level rise of 3 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 49)
16. **Sea level rise of 3 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 3 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 50)
17. **Sea level rise of 4 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 51)
18. **Sea level rise of 4 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 52)

19. **Sea level rise of 4 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 53)
20. **Sea level rise of 4 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 4 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 54)
21. **Sea level rise of 5 ft + 3-day 25-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 55)
22. **Sea level rise of 5 ft + 1-day 100-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 56)
23. **Sea level rise of 5 ft + 1-day 10-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 57)
24. **Sea level rise of 5 ft + 1-day 5-year storm** (only coastal area and GW affected – GW layer rises 5 ft)**.** Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (Figure 58)

In all cases, a great amount of flooding is noted along the waterbodies and wetlands. As this basin connects to the ocean though Rocky Bayou, SLR scenarios plays an important hole, implying a considered growth as the projected scenario of rising tides rises.

The design storm simulation determined that approximately 5.7% of the HUC total area or 1.11 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 3.5% of the HUC's total area, or 0.67 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 4.6% of the HUC's total area, or 0.91 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 3.9% of the HUC's total area, or 3.9 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401020504 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	18.39	1.11	94.3%	5.7%
1-day 100-year	18.83	0.67	96.5%	3.5%
1-day 10-year	18.60	0.91	95.4%	4.6%
1-day 5-year	18.74	0.77	96.1%	3.9%

2.5 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.:

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.5.1 Results

Error! Reference source not found. to **Error! Reference source not found.**depict the HUC 031401020504 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 60) overlays critical facilities onto the 1-day 100-year storm event scenario, while the third map (**Error! Reference source not found.**) represents the same overlay within the context of 5 feet of sea level rise (SLR) combined with the 1-day 100-year storm event. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 5 feet SLR + 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** and **Error! Reference source not found.** illustrate the composite score for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. **Error! Reference source not found.** represents the calculation for composite score based on 1-day 100-year storm event, while **Error! Reference source not found.** shows the calculation for composite score for the same storm event, but including a 5 feet of Sea Level Rise scenario. **Error! Reference source not found.** shows the same area zoomed out.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.5.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020504. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.5.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401020504. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401020504	12485.20
All of the 1-day 100-year storm event inundation	**431.46**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	331.44
B. Federal Land in 1-day 100-year inundation > 10 acres	100.01
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	0.00
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	0.00

2.5.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not**

found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

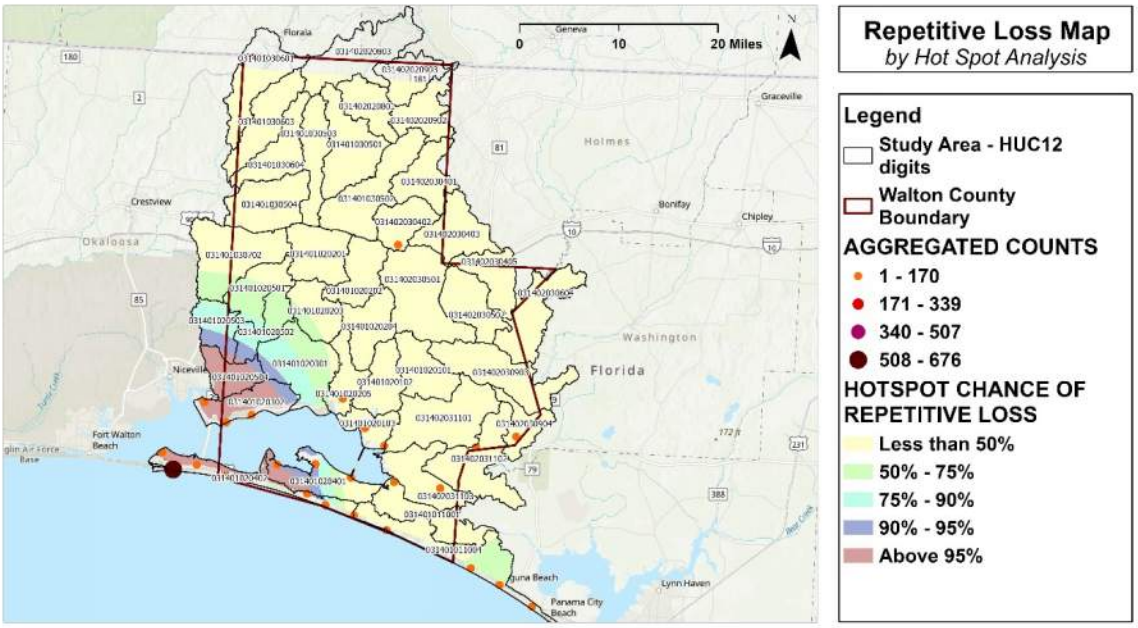

Figure 66. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.5.5 Priority Projects

The entire HUC area is undeveloped. As a result, there are no critical facilities or other land uses that require priority for intervention. The flooding is substantial as it is a coastal area, but not alarming since there is no proprieties being impacted. Therefore, the composite score is null, indicating that there is no pressing priority for interventions to address inundation impact within the basin.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030501) is highlighted among all the HUCs to help identifying its location.

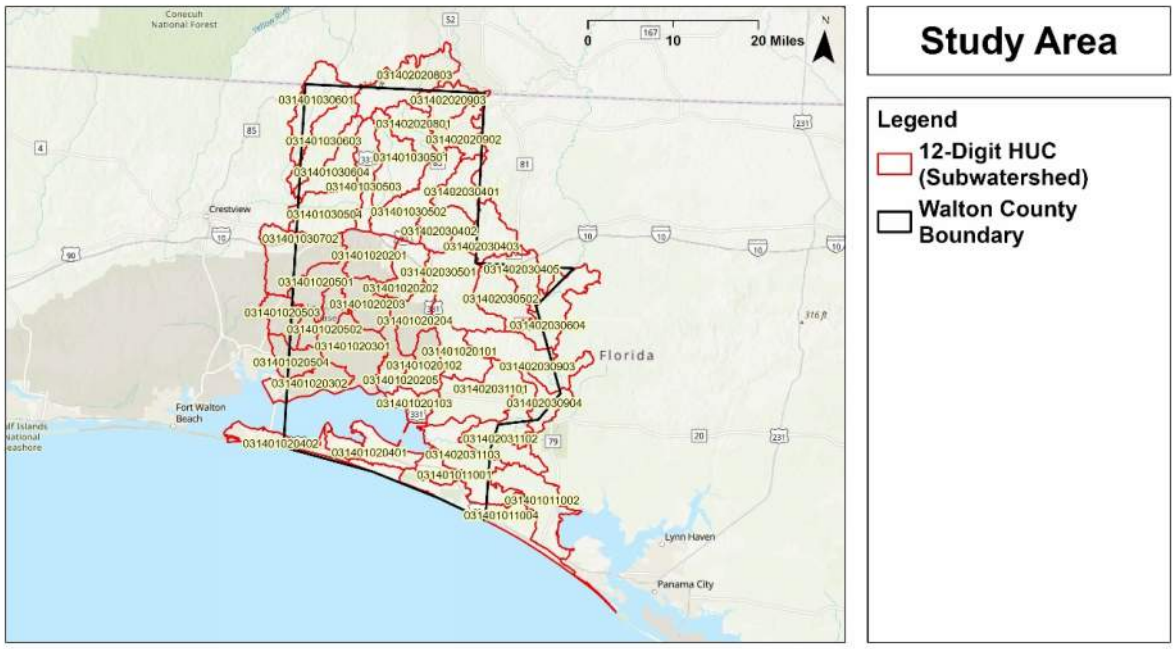

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

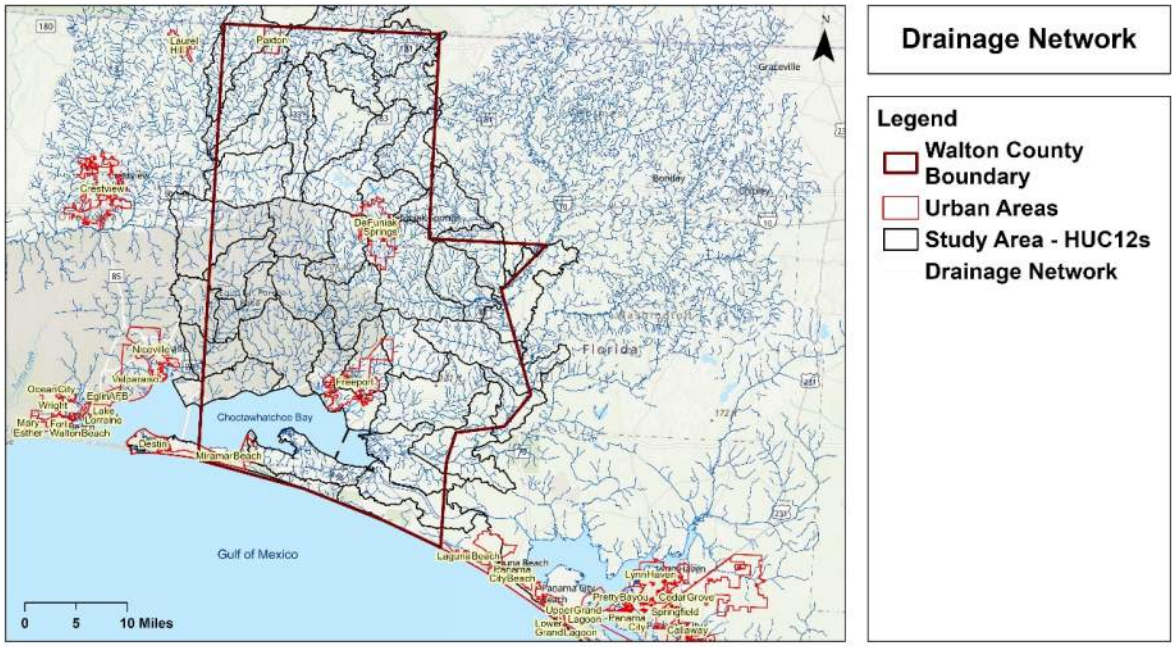

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

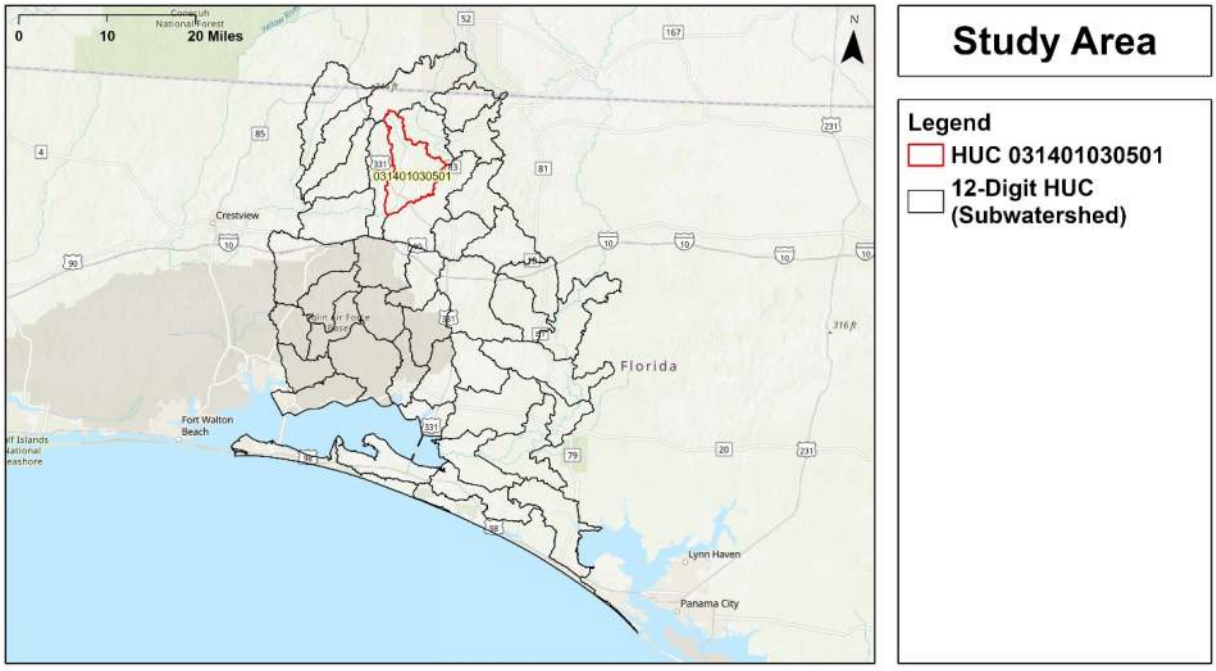

Figure 3. HUC 031401030501 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding.

The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

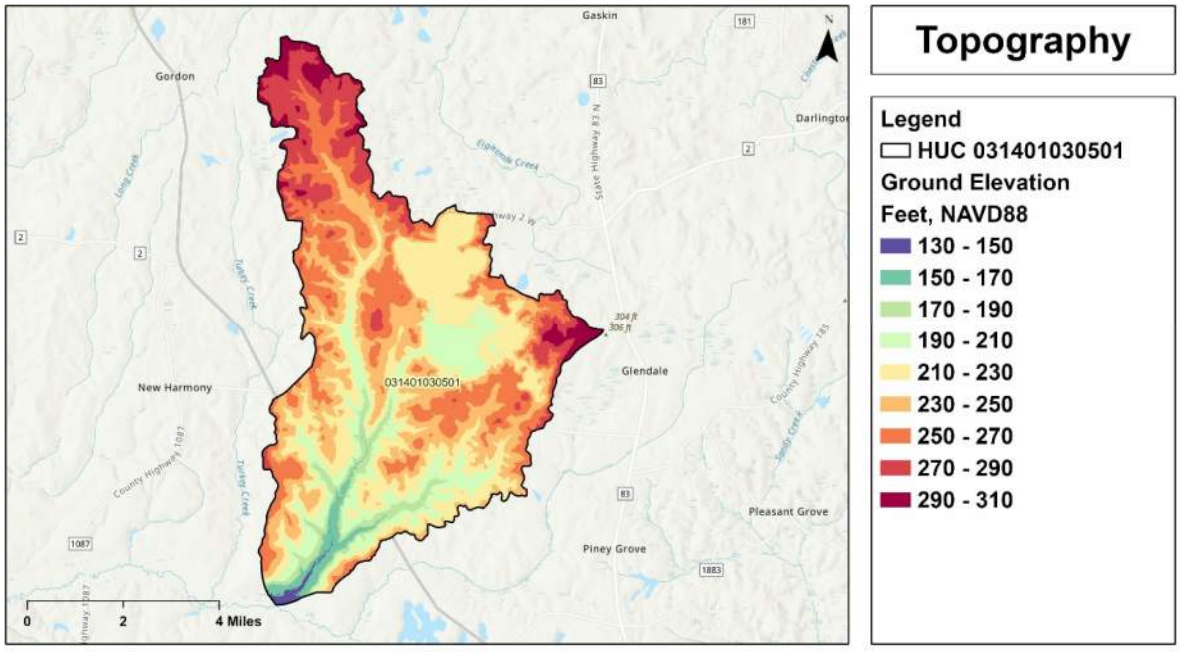

Figure 4. Topographic map of the HUC 031401030501 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030501 sub-watershed is shown in **Error! Reference source not found.**.

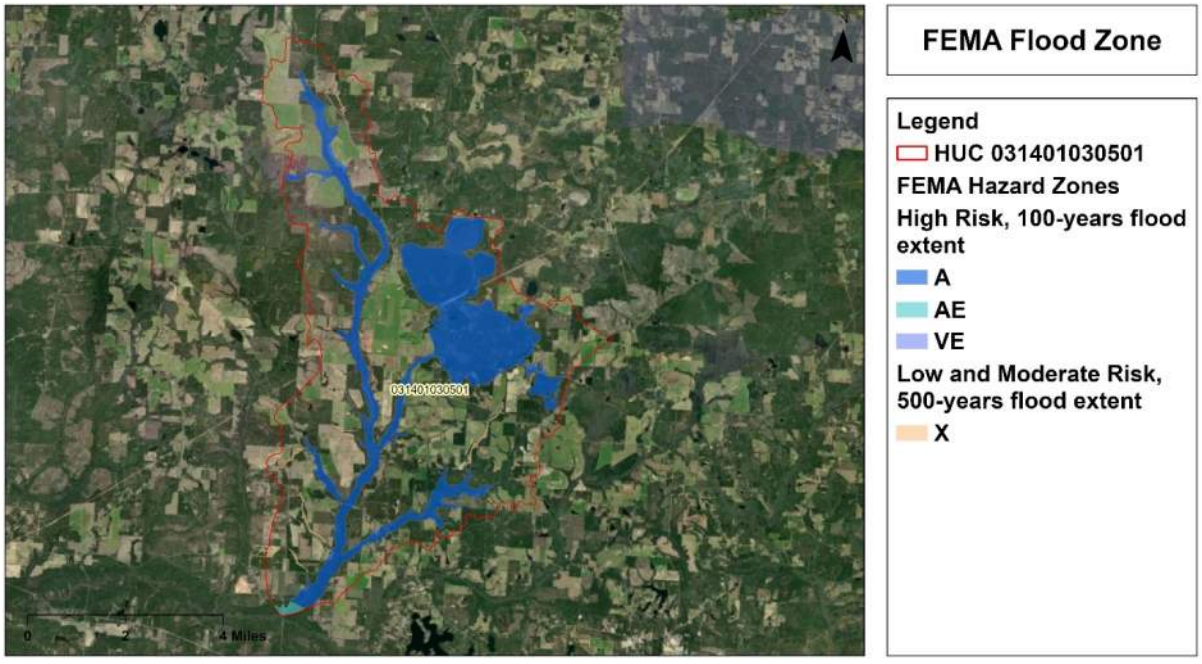

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030501 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030501 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

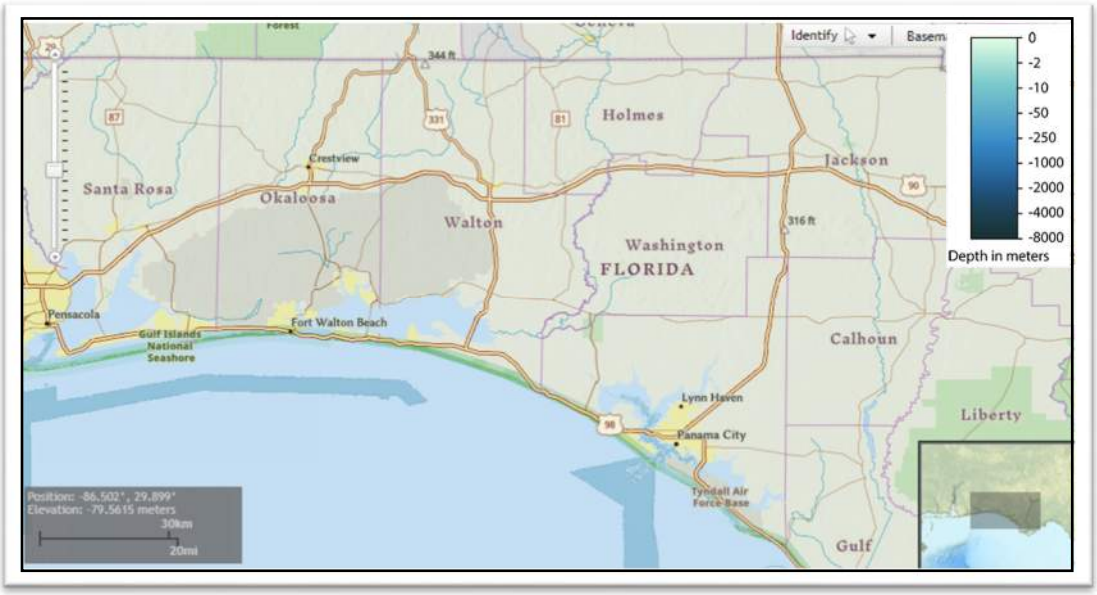

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

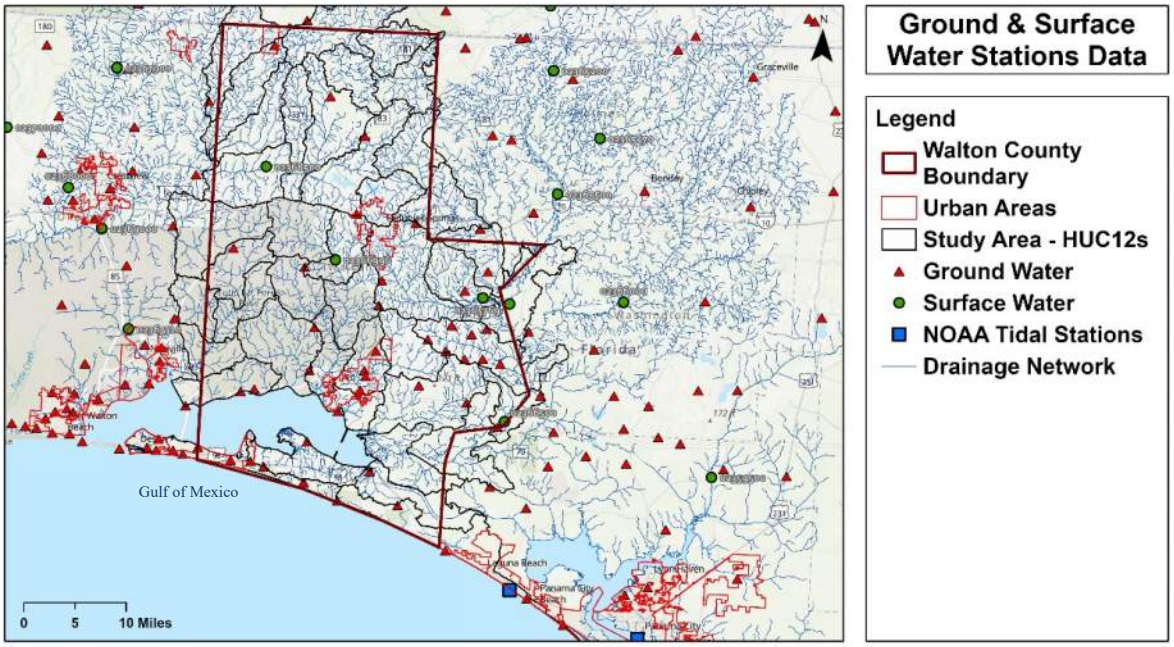

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030501 has no major rivers and canals, but creeks and branches, include:

- Rocky Creek
- Bear Branch

- Dogwood Head Branch
- Green Head Branch
- Exline Creek
- Wildcat Creek
- Mount Sinai Branch

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030501, which is USGS 02368500 Shoal River NR Mossy Head, FLA.

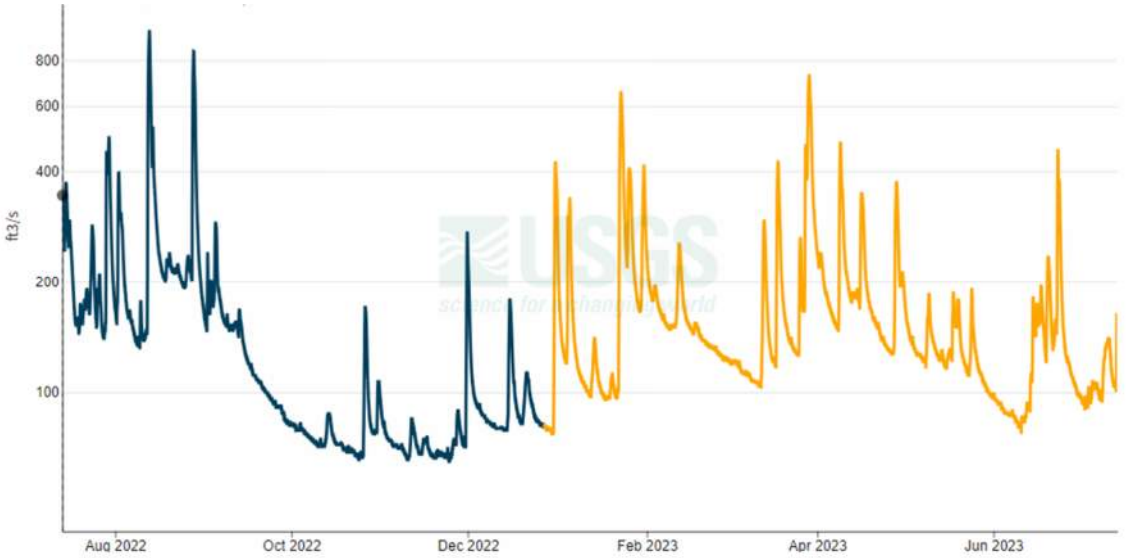

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla. – 02368500
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are

estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030501 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401030501 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

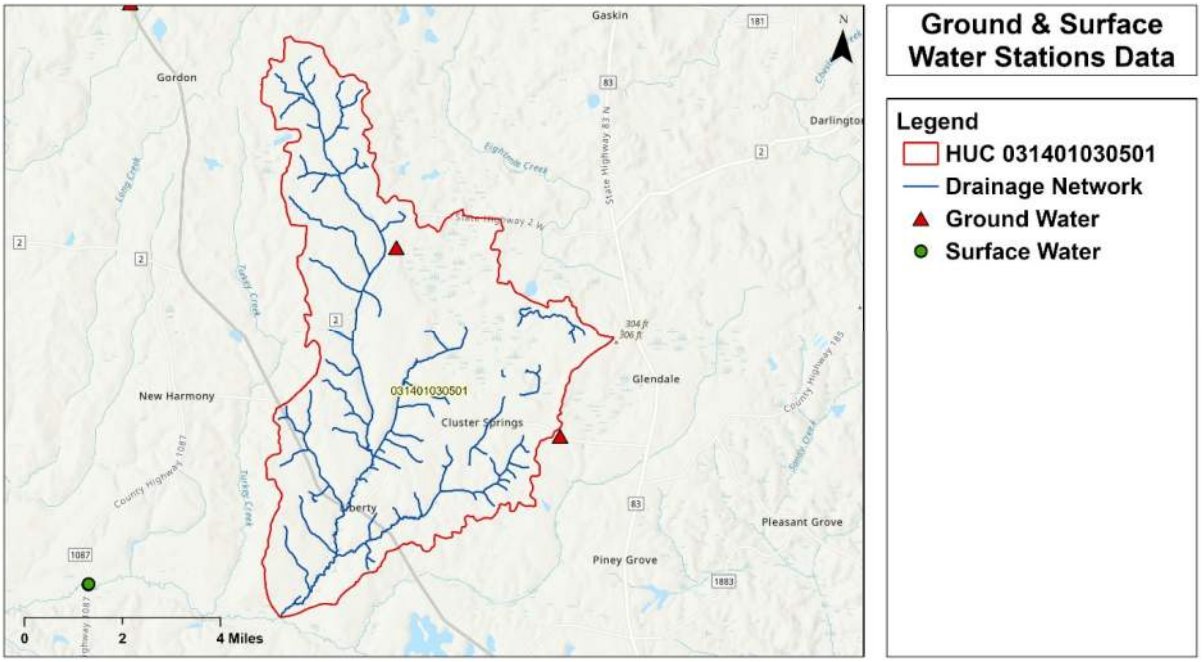

Figure 9. Ground and Surface Water Stations in the HUC 031401030501 sub-watershed, processed by FAU.

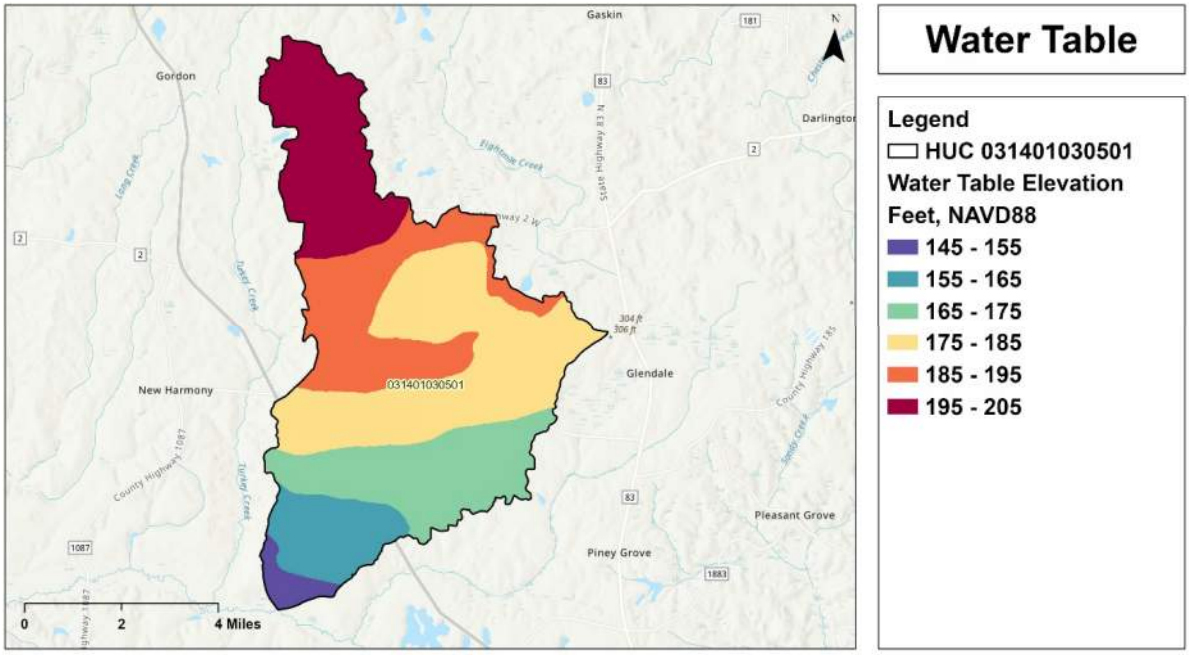

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030501 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

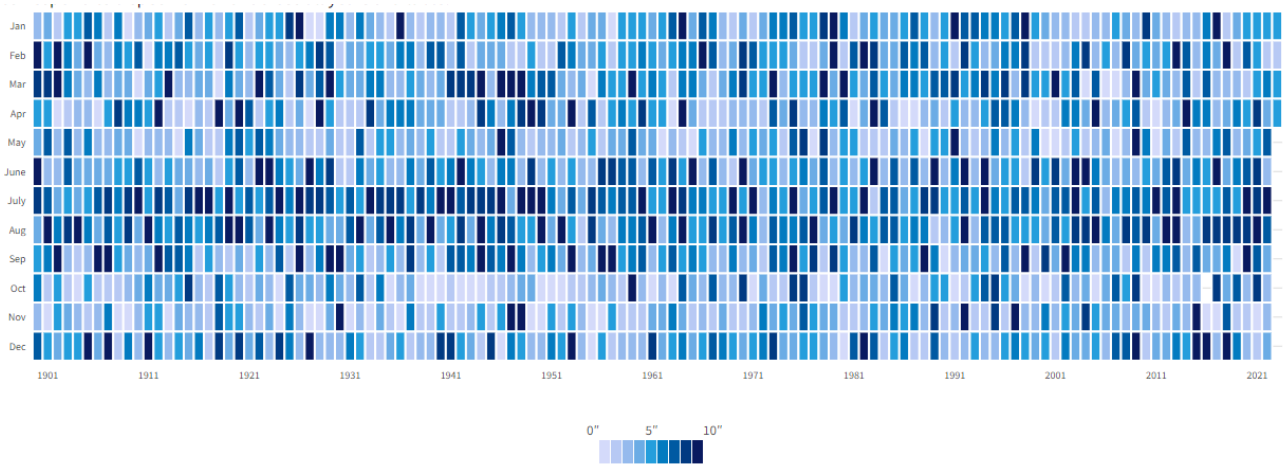

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

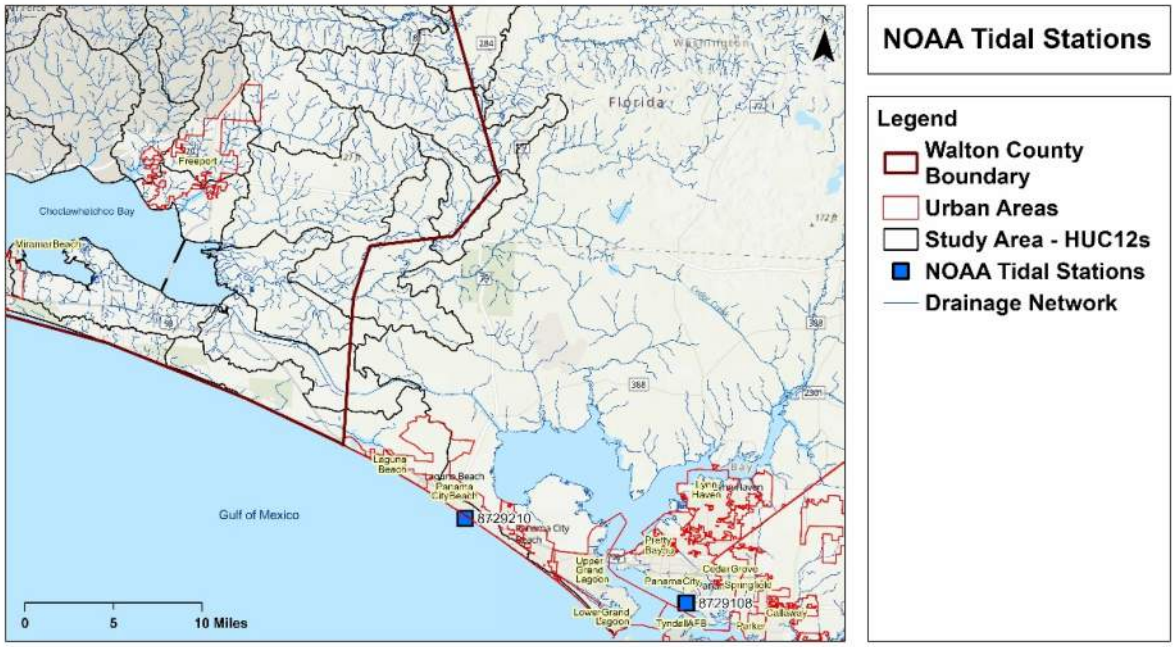

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**..

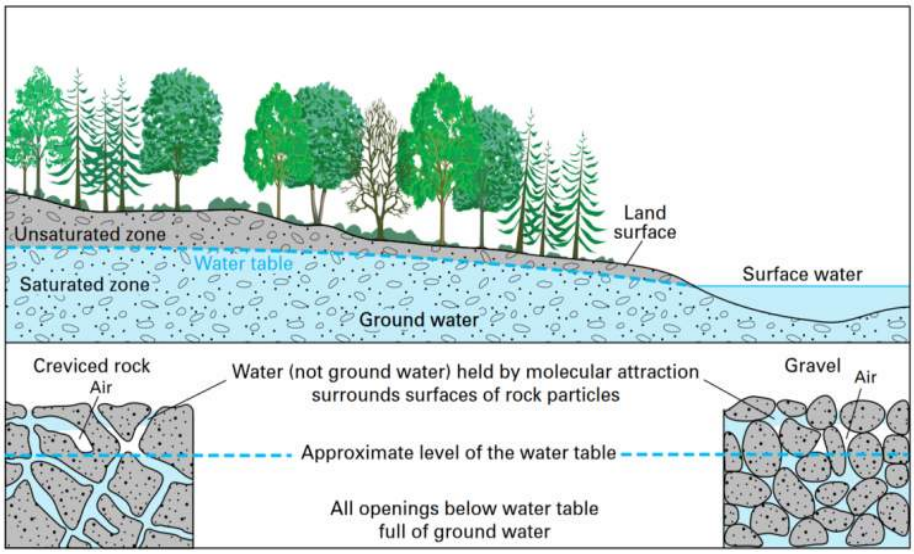

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

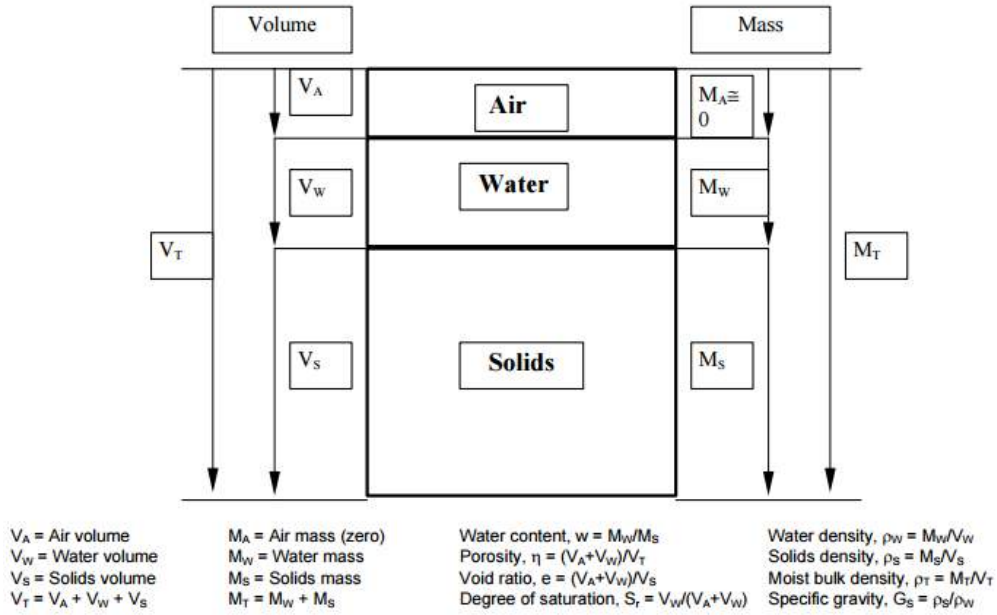

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

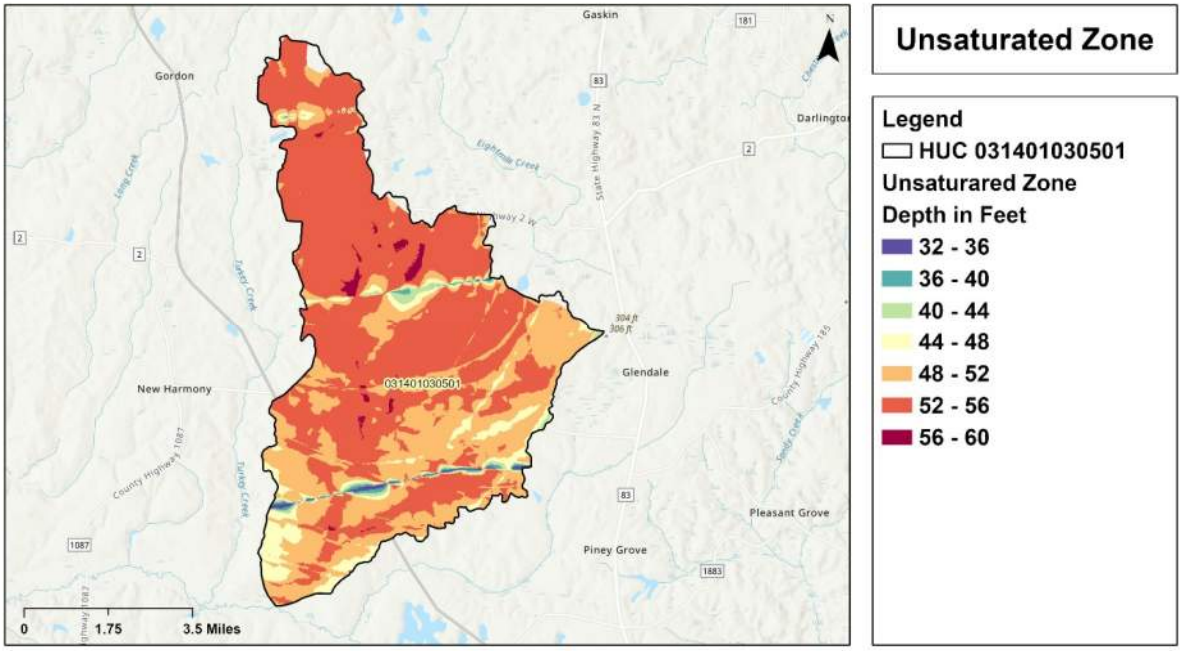

Figure 15. Unsaturated zone map for HUC 031401030501, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. Much of the basin has a medium amount of soil storage capacity, ranging between 30 to 33 inches of capacity left.

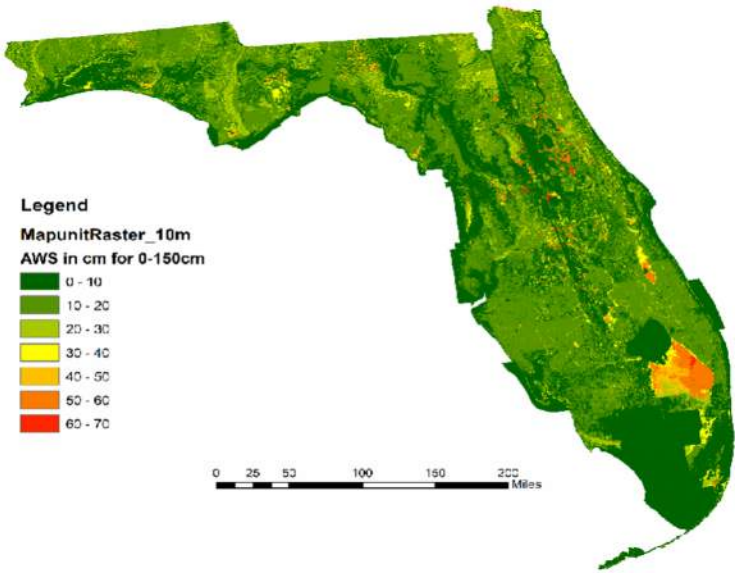

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

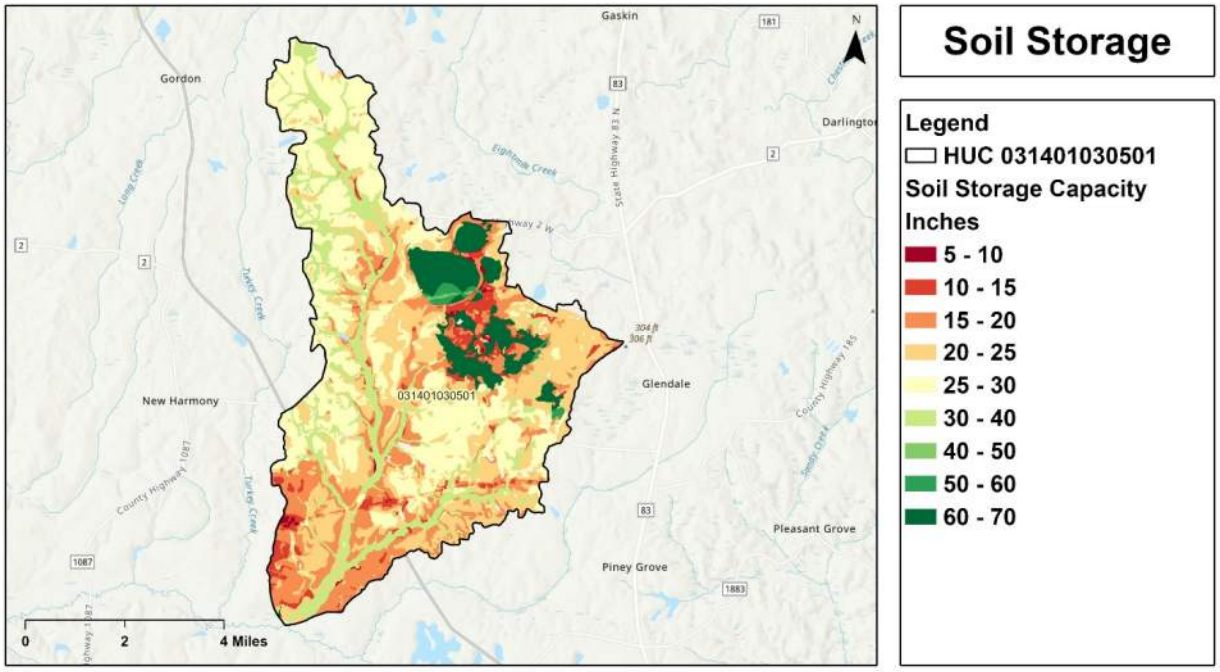

Figure 17. Water storage capacity of soil for the HUC 031401030501 (inches), processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

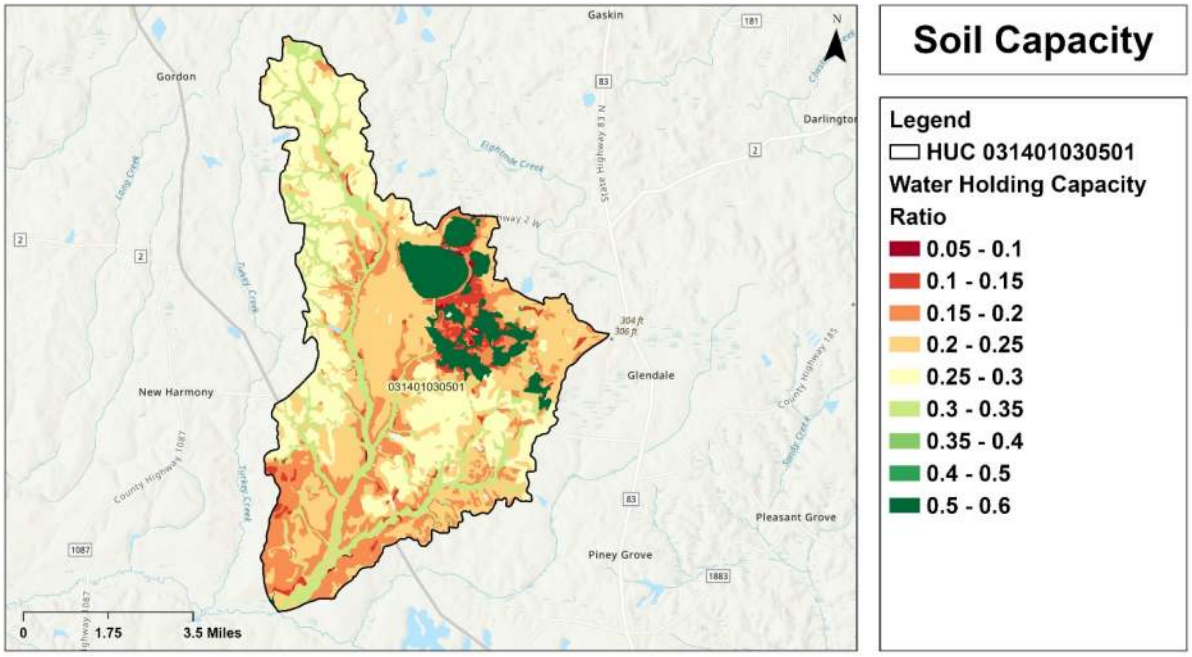

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030501, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

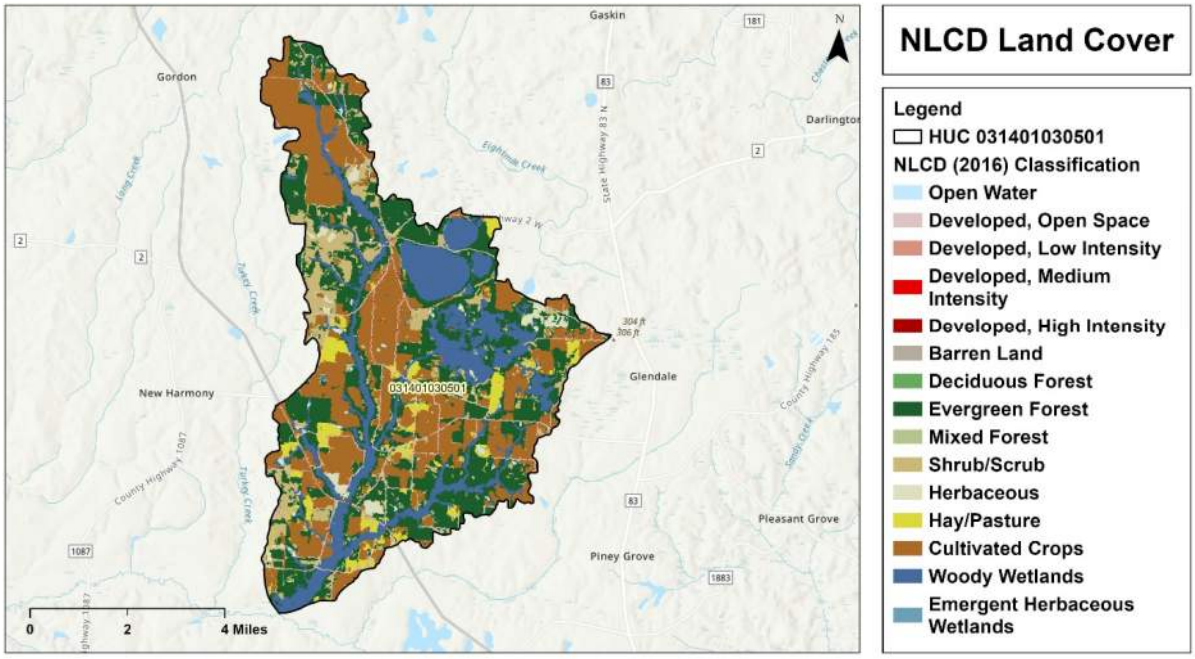

Figure 19. Land use in the HUC 031401030501 (from the NLCD 2016 database), processed by FAU.

In the HUC 031401020203 sub-watershed, the predominant land cover is upland forest, accounting for 62.90% of the area. Urban and built-up comes in second at 13.92%, followed by wetlands at 10.80%, and rangeland at 9.73%, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

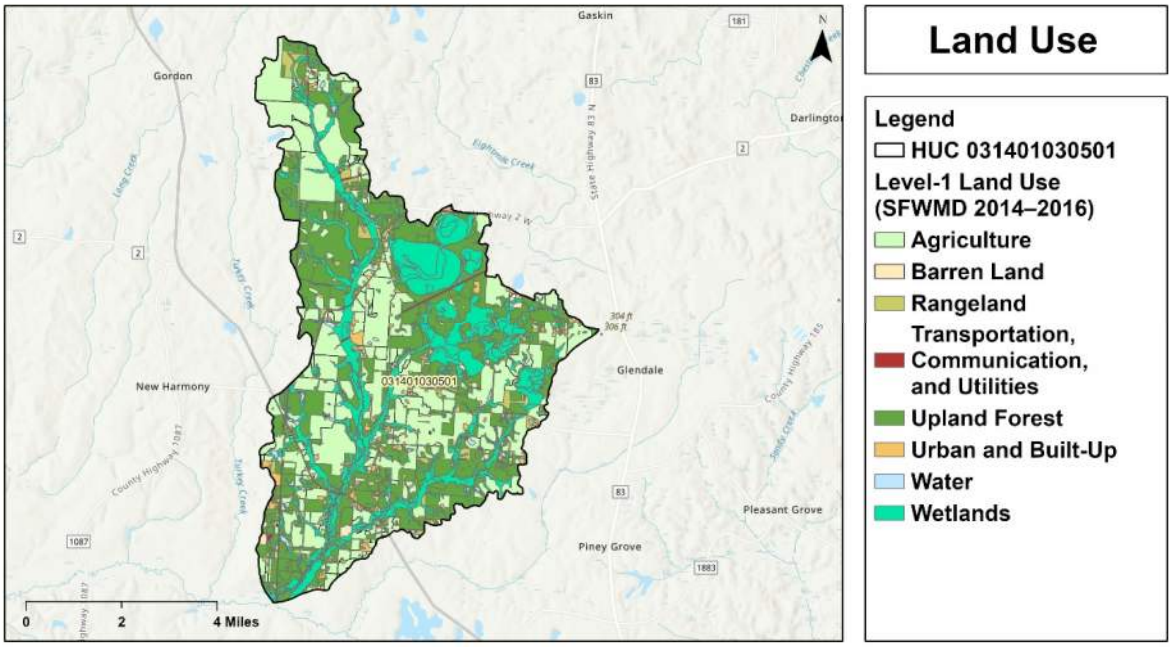

Figure 20. Land use in the HUC 031401030501 (2023 Florida Geographic Data Library (FGDL)), processed by FAU.

In the HUC 031401030501 sub-watershed, the predominant land cover is upland forest, accounting for 37.80% of the area. Agriculture comes in second at 31.26%, followed by wetlands at 16.50%, and Transportation, Communication, and Utilities at 8.06%. Developed land constitutes a minor portion, with only 2.42% categorized as urban and built-up, as indicated in Table 3.

Table 3. Land use for HUC 031401030501 subwatershed (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	11614.09	31.26%
Barren Land	179.10	0.48%
Rangeland	761.86	2.05%
Transportation, Communication, and Utilities	2995.04	8.06%
Upland Forest	14041.44	37.80%
Urban and Built-Up	899.12	2.42%
Water	528.62	1.42%
Wetlands	6130.98	16.50%
Grand Total:	**37150.25**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

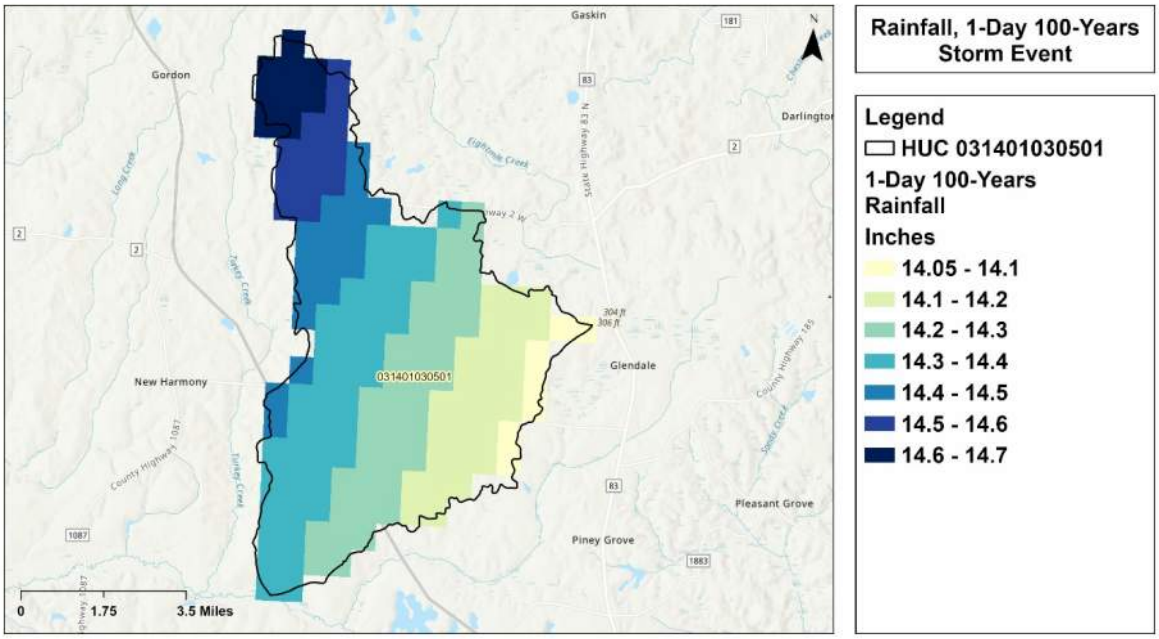

Figure 22. Rainfall distribution map across HUC 031401030501 sub-watershed, for 1-day 100-year storm event, processed by FAU.

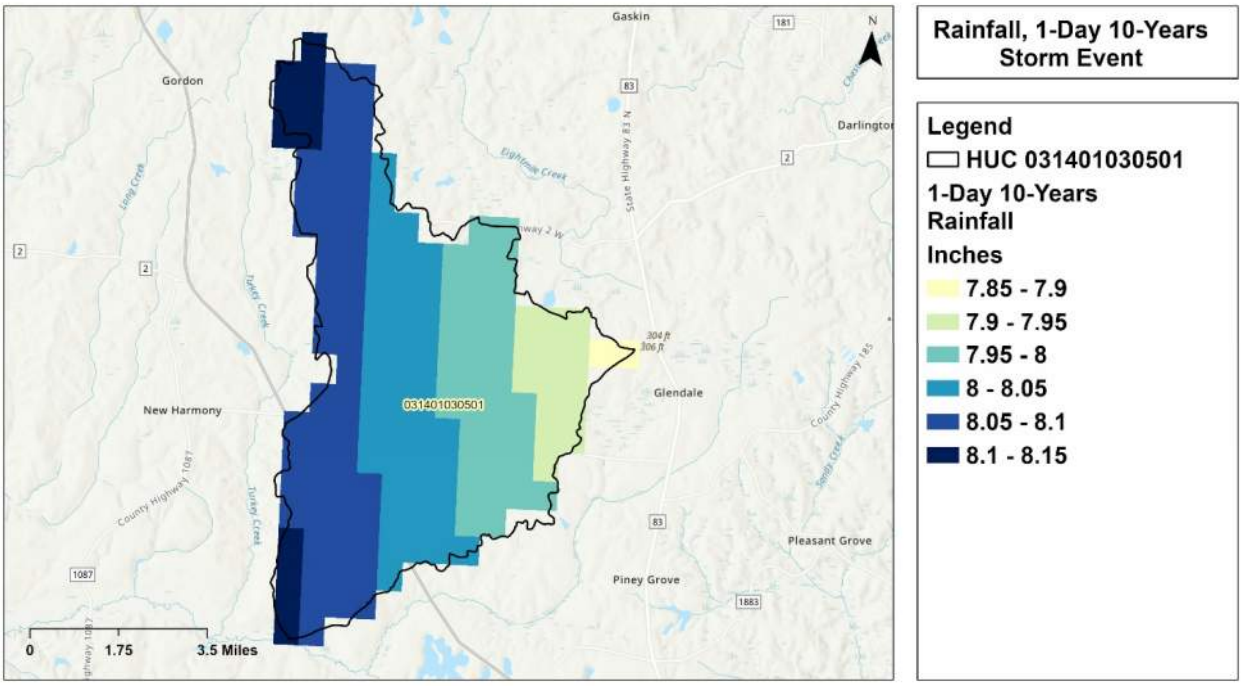

Figure 23. Rainfall distribution map across HUC 031401030501 sub-watershed, for 1-day 10-year storm event, processed by FAU.

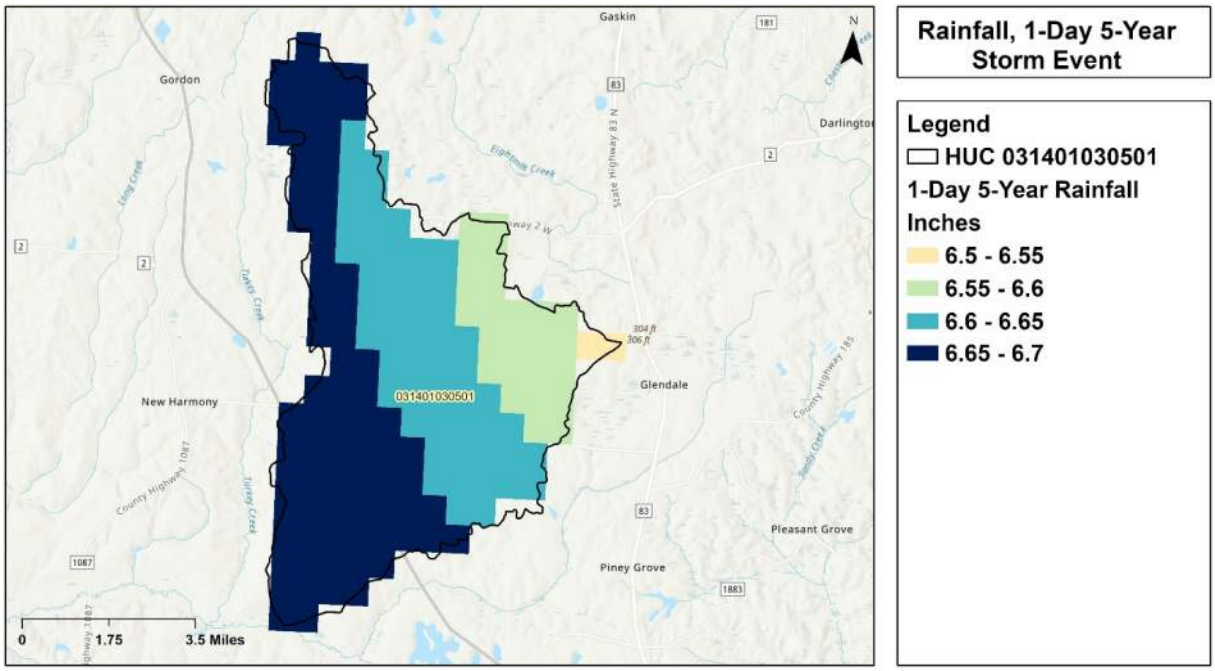

Figure 24. Rainfall distribution map across HUC 031401030501 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land

cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

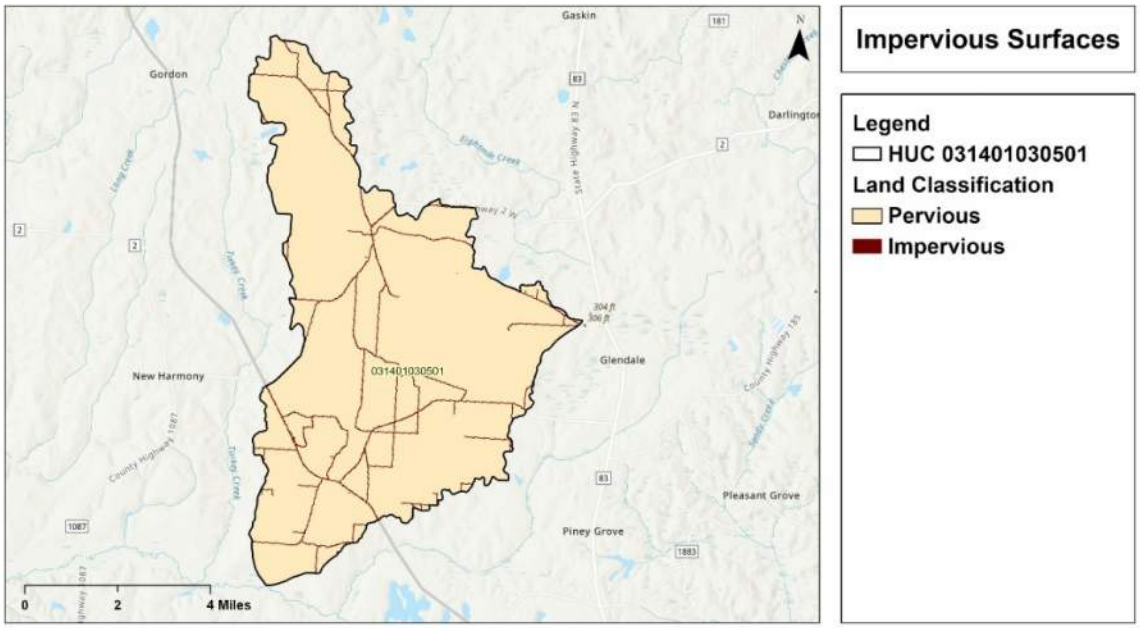

Figure 25. Impervious area map for the HUC 031401030501 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

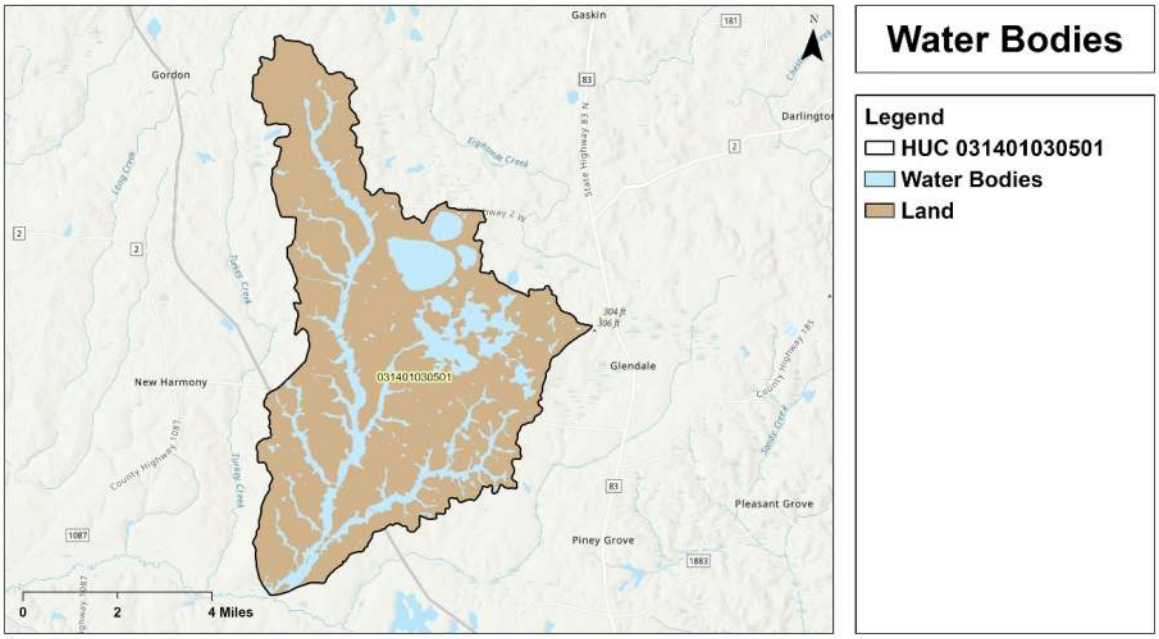

Figure 26. Water bodies map for the HUC 031401030501 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

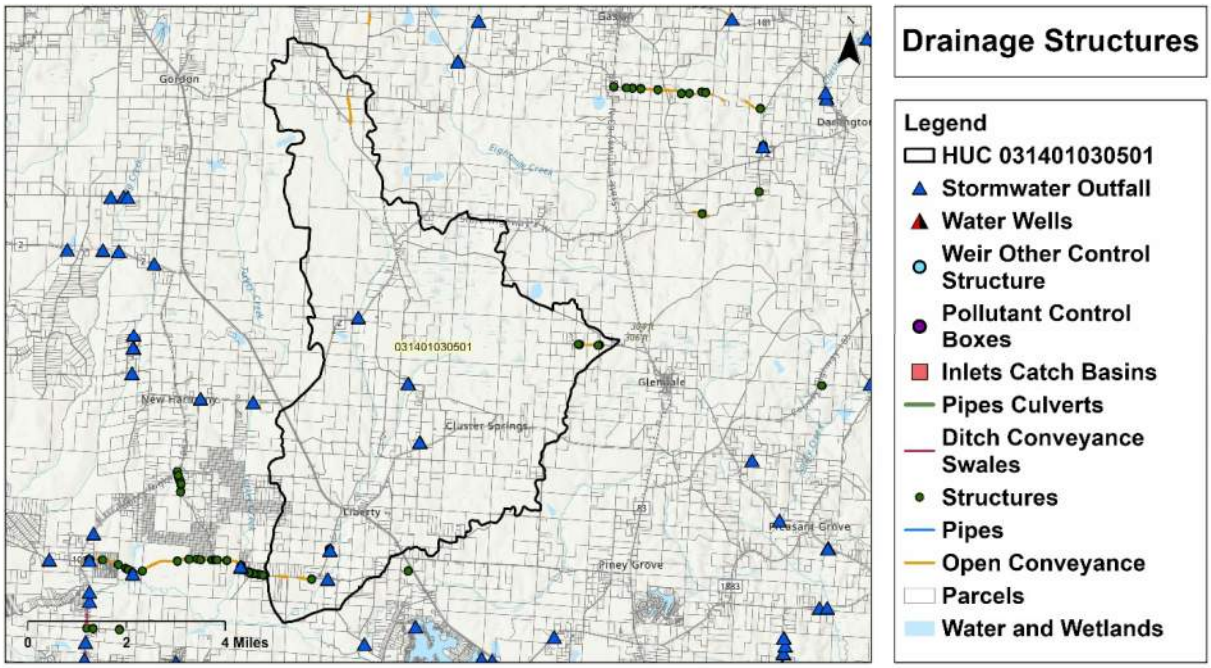

Figure 27. Stormwater Infrastructure for the HUC 031401030501. Processed by FAU.

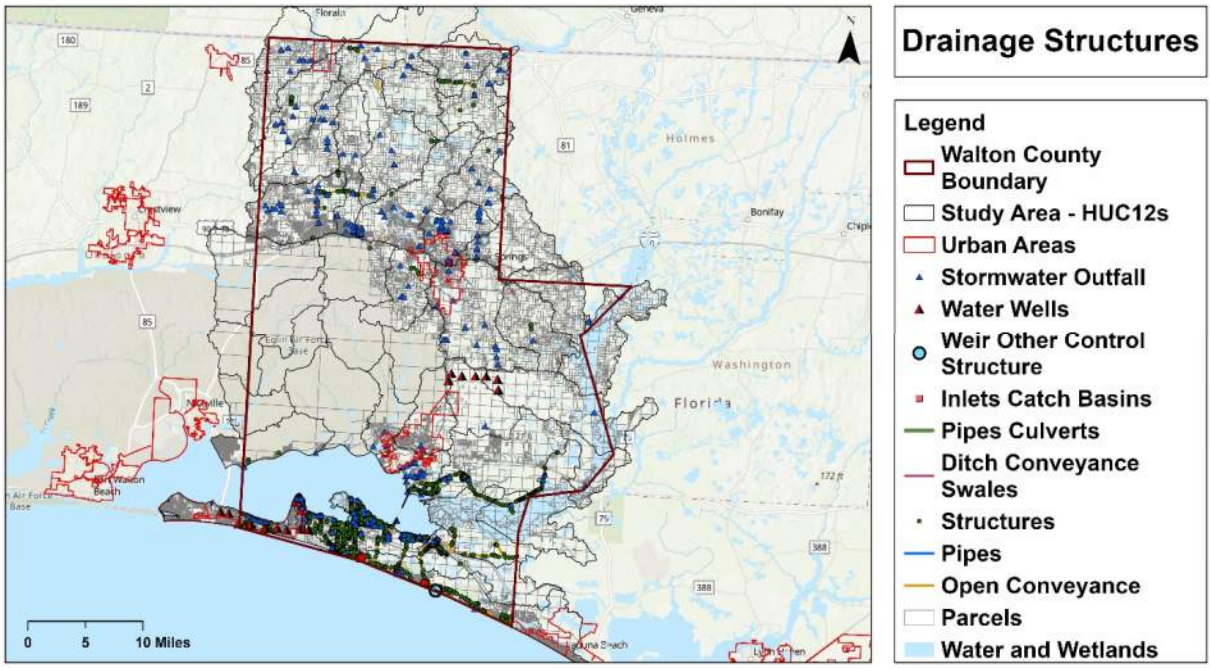

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030501 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the

coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. Figure 29 shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

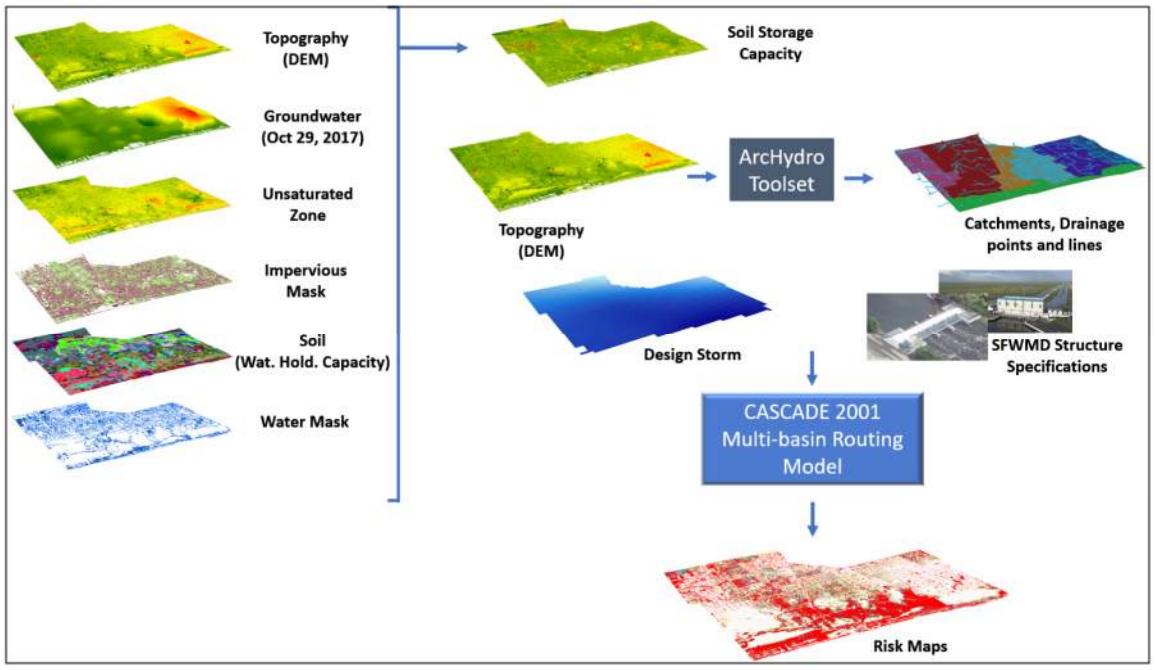

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

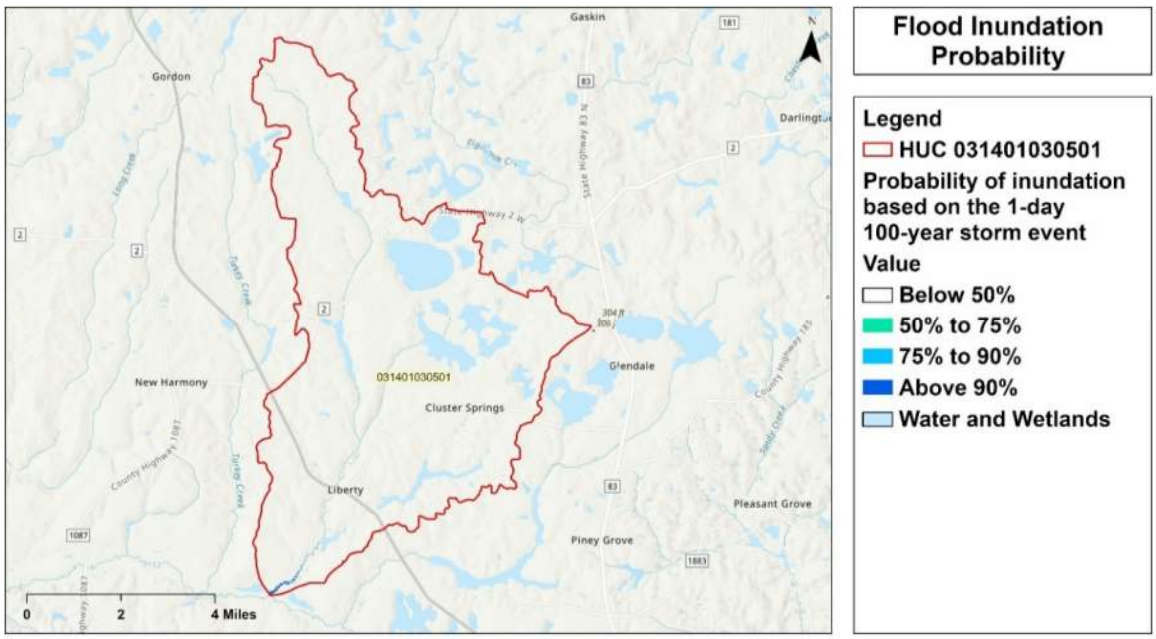

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030501, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is

used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed later in this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a very small portion of flooding is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.1% of the HUC total area or 0.02 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.1% of the HUC's total area, or 0.04 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.1% of the HUC's total area, or 0.02 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0% of the HUC's total area, or 0.01 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030501 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	41.90	0.02	99.9%	0.1%
1-day 100-year	41.88	0.04	99.9%	0.1%
1-day 10-year	41.90	0.02	99.9%	0.1%
1-day 5-year	41.91	0.01	100.0%	0.0%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5

70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401020203 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.**is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.**illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

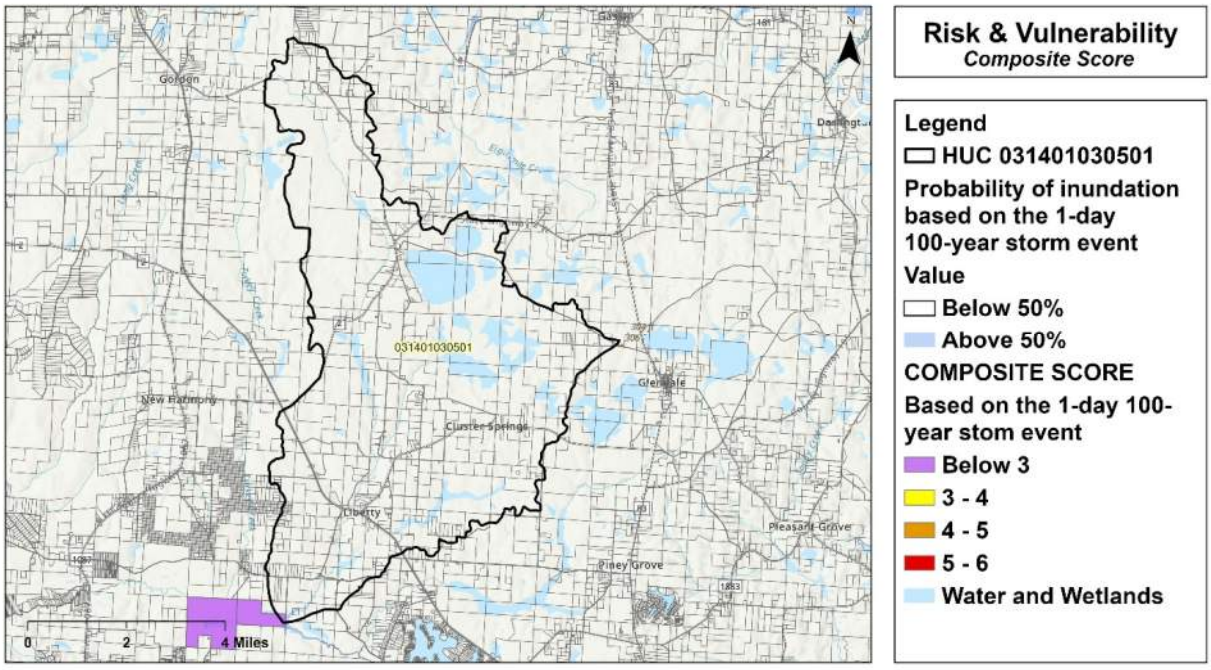

Figure 38. HUC 031401030501 sub-watershed Composite Score Risk map, calculation based on 1-day 100-year storm event. Processed by FAU.

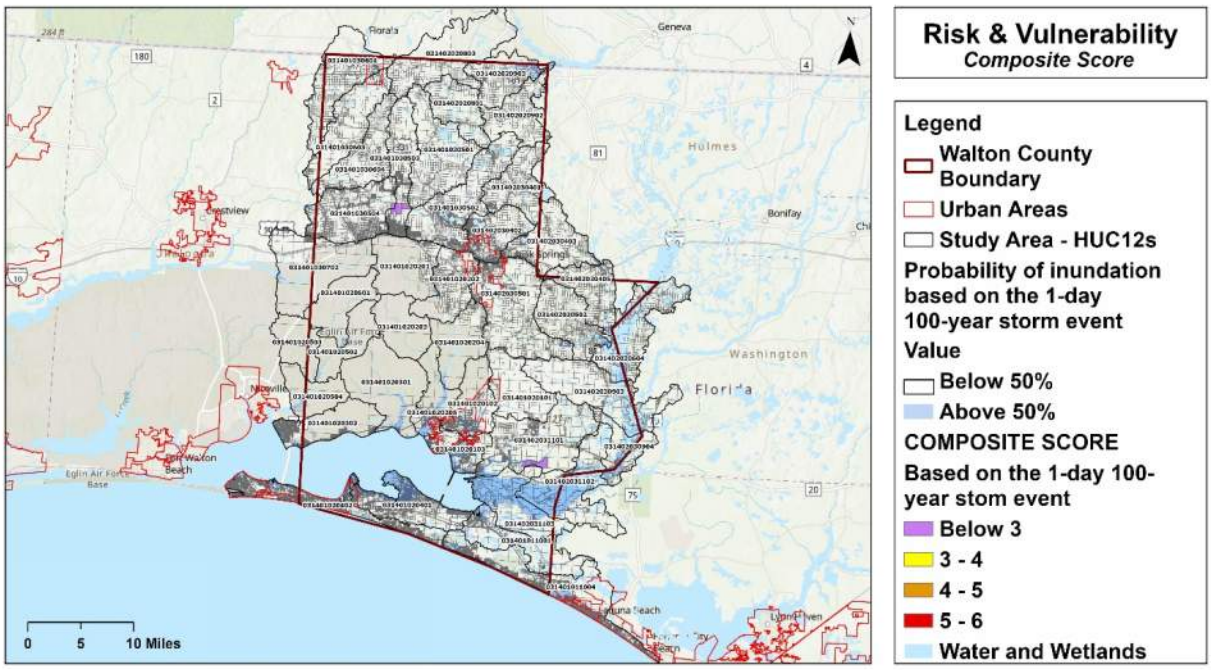

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401020203. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030501. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030501	26830.11
All of the 1-day 100-year storm event inundation	**25.00**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	25.00
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	25.00

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not**

found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

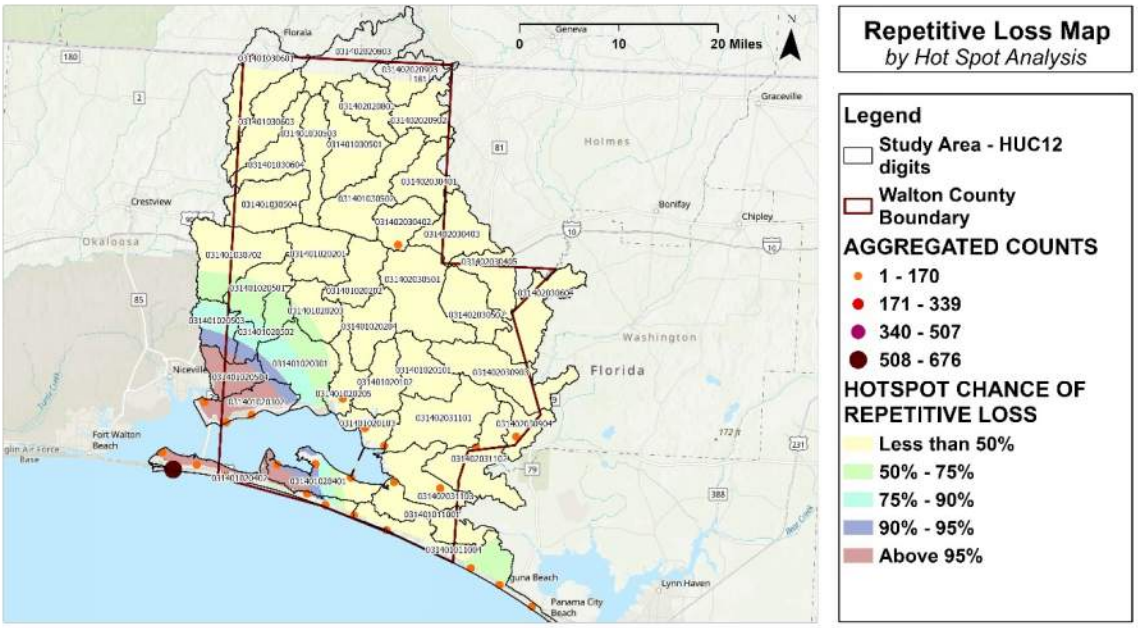

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are a few parcels falling within classification tier 1 and 4 and a good amount of parcels falling within 5 priority of land uses, none of them are within the flooding zone, once flooding in the area is relatively minor and not alarming. Consequently, when considering the composite score, it notable that there are no critical facilities situated within the flooding zone, indicating no necessity for priority projects intervention within the basin.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (Figure 1). Figure 2 shows Walton County Drainage Network and the location of urban areas (cities and towns). In Figure 3, the HUC-12 digits (031401030502) is highlighted among all the HUCs to help identifying its location. (Figure 3).

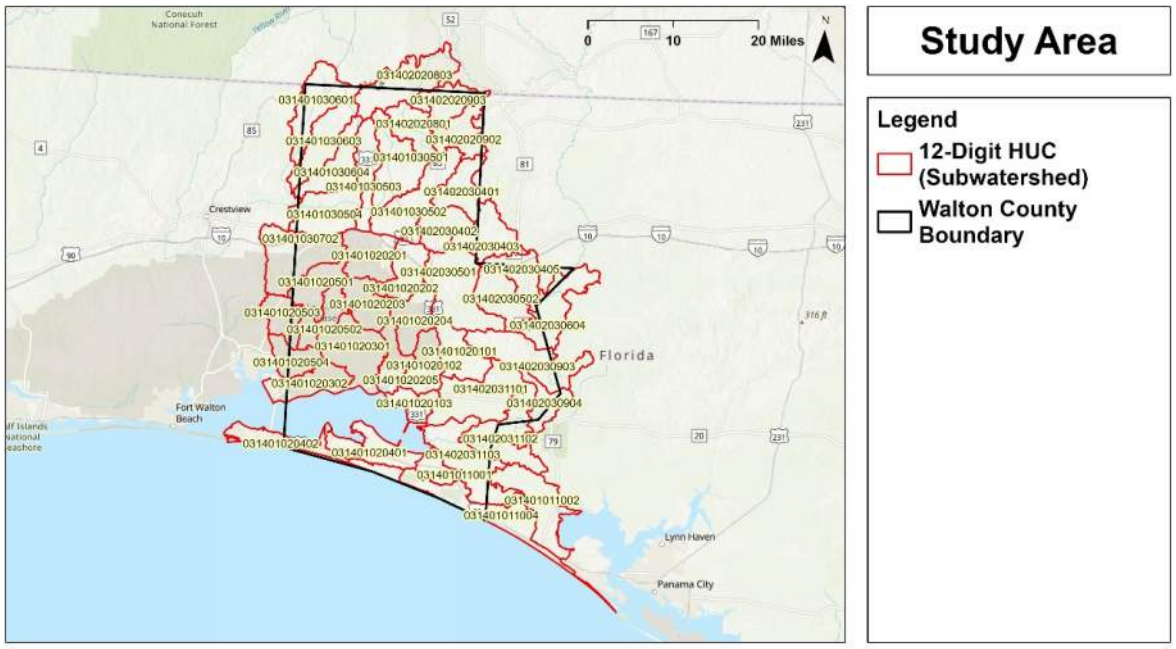

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

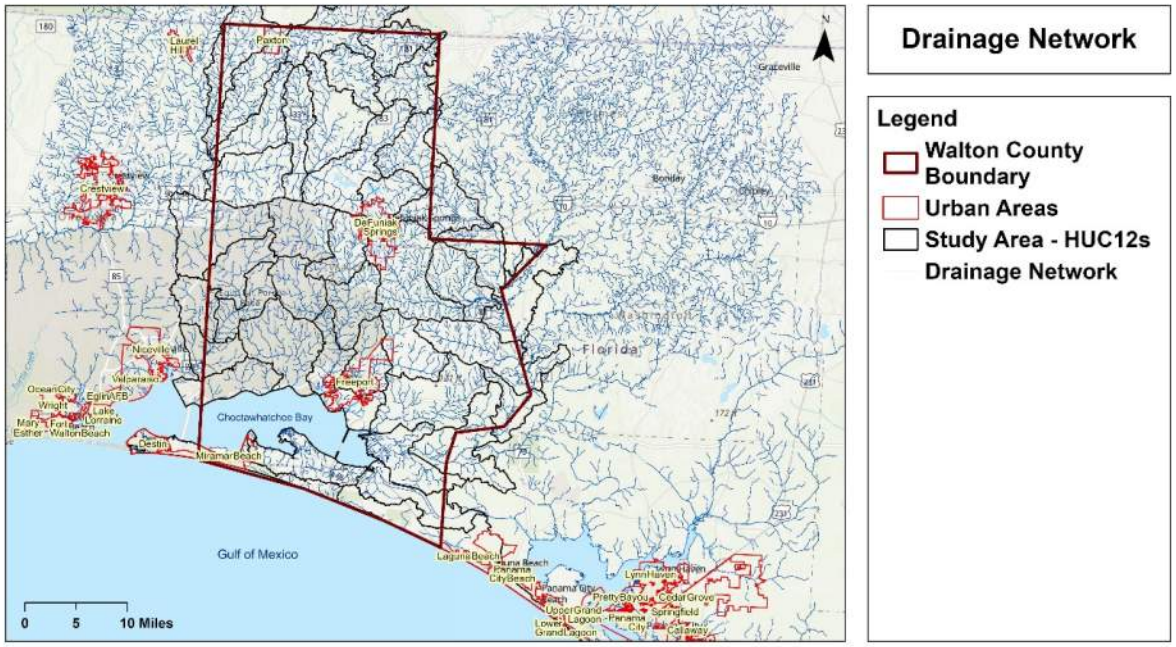

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

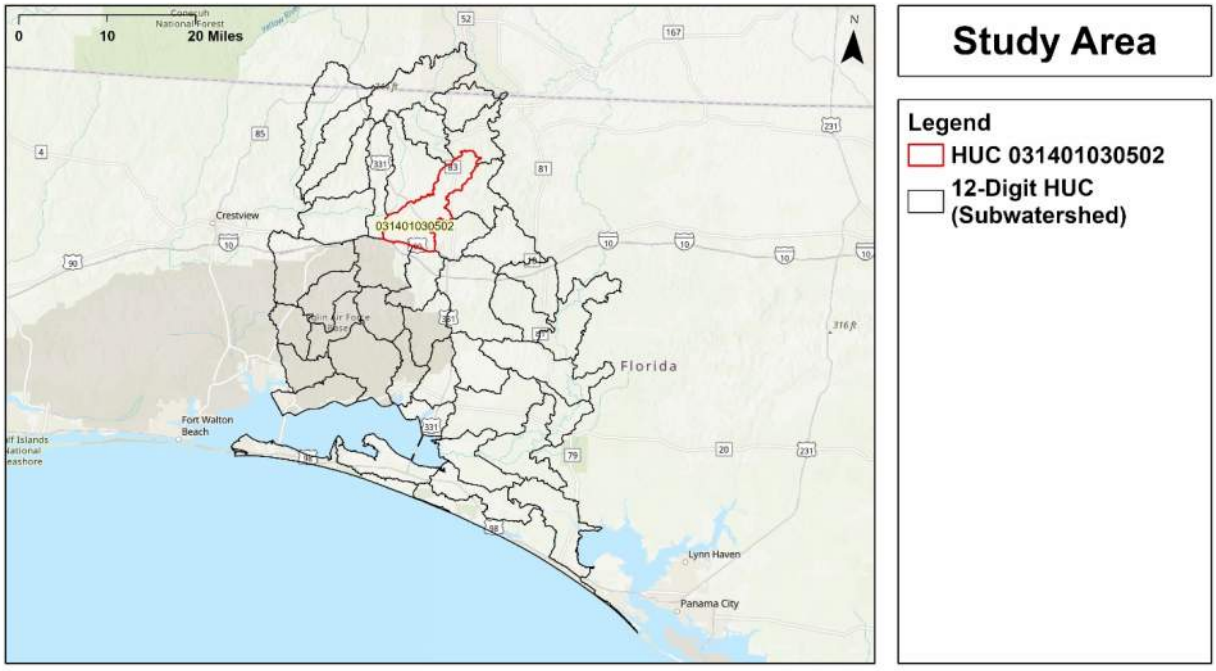

Figure 3. HUC 031401030502 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Figures 12 and 13 in the county-wide report show the current and projected land use for the County. Based on the 2017 future land use map for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.9	7.17%
Barren Land	9242.1	1.25%
Rangeland	40326.7	5.46%
Transportation, Communication, and Utilities	11815.7	1.60%
Upland Forest	356796.1	48.30%
Urban and Built-Up	52194.8	7.07%
Water	61593.9	8.34%
Wetlands	153759.9	20.82%
Total	**738687.9**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the

potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

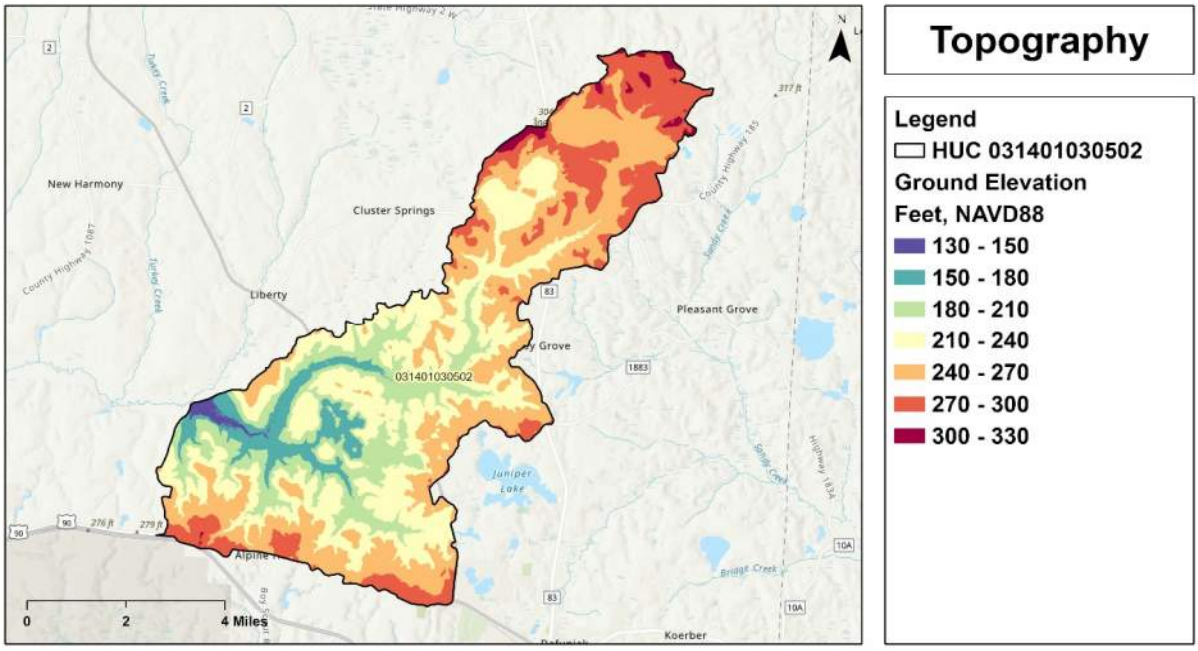

Figure 4. Topographic map of the HUC 031401030502 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030502 sub-watershed is shown in **Error! Reference source not found.**.

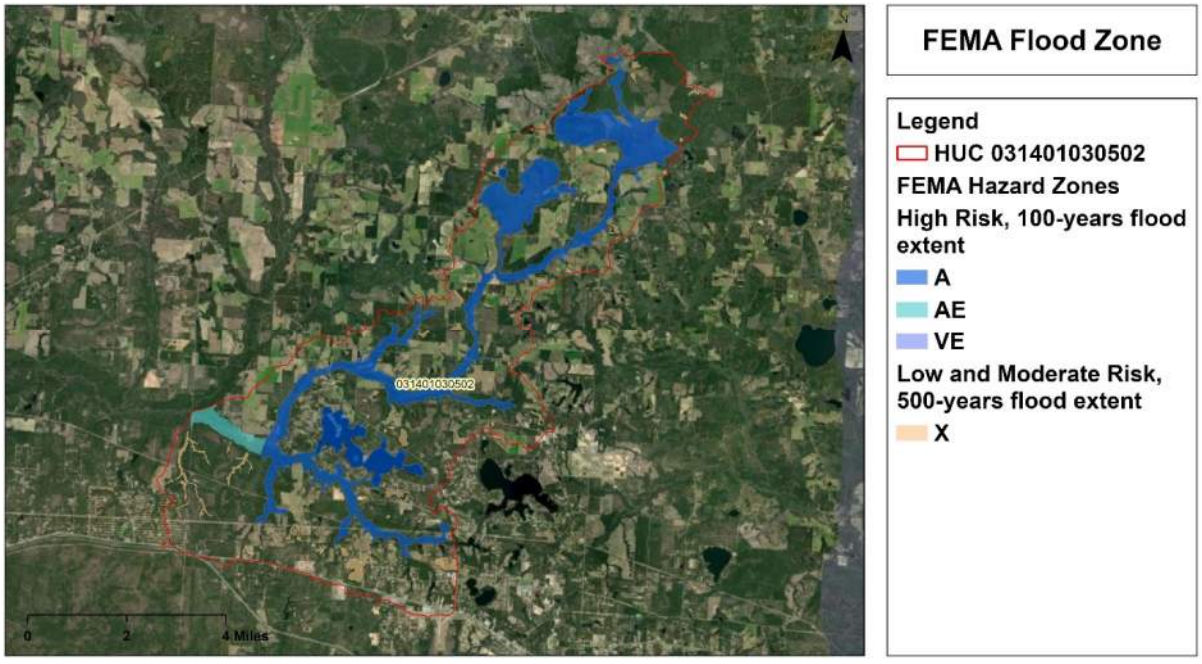

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030502 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030502 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

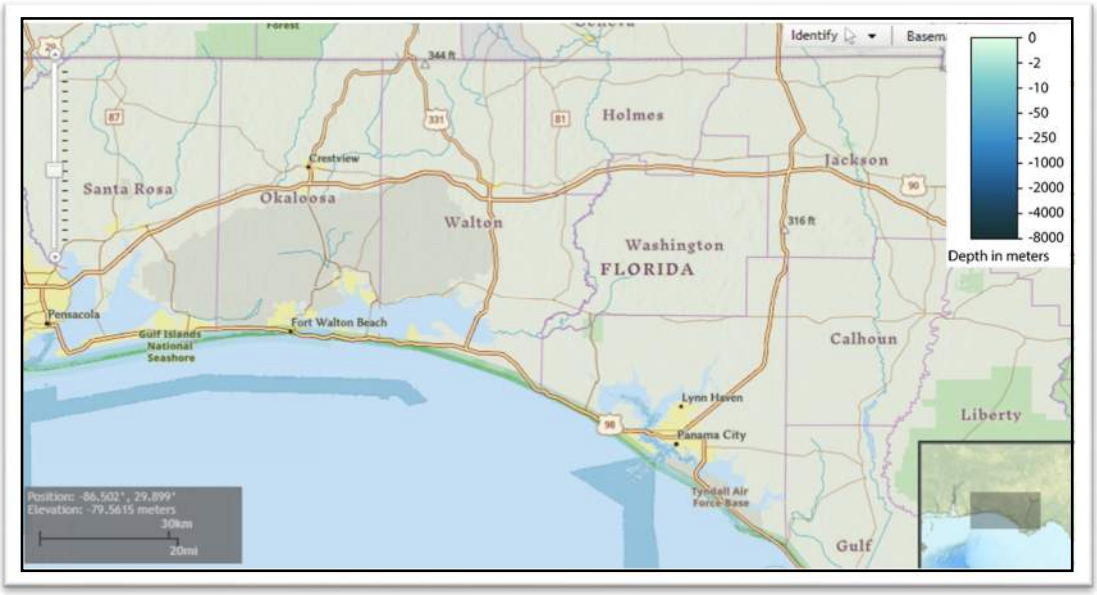

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

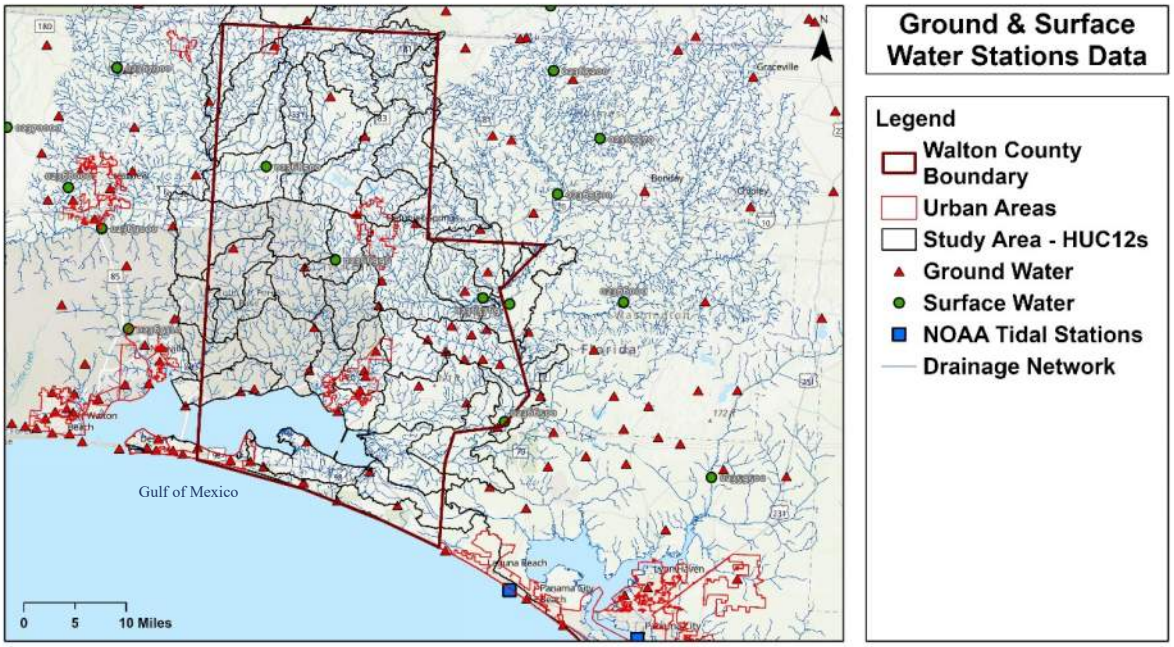

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030502 has no major rivers and canals, but creeks and branches include:

- Rocky Creek
- Schoolhouse Branch
- Fox Branch

- Yellow Root Branch
- Old Peg Branch
- Bear Bay Branch
- Bully Horselot Branch
- East Rocky Creek
- Mattress Head Branch
- Open Branch

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030502, which is USGS 02368500 Shoal River NR Mossy Head, FLA.

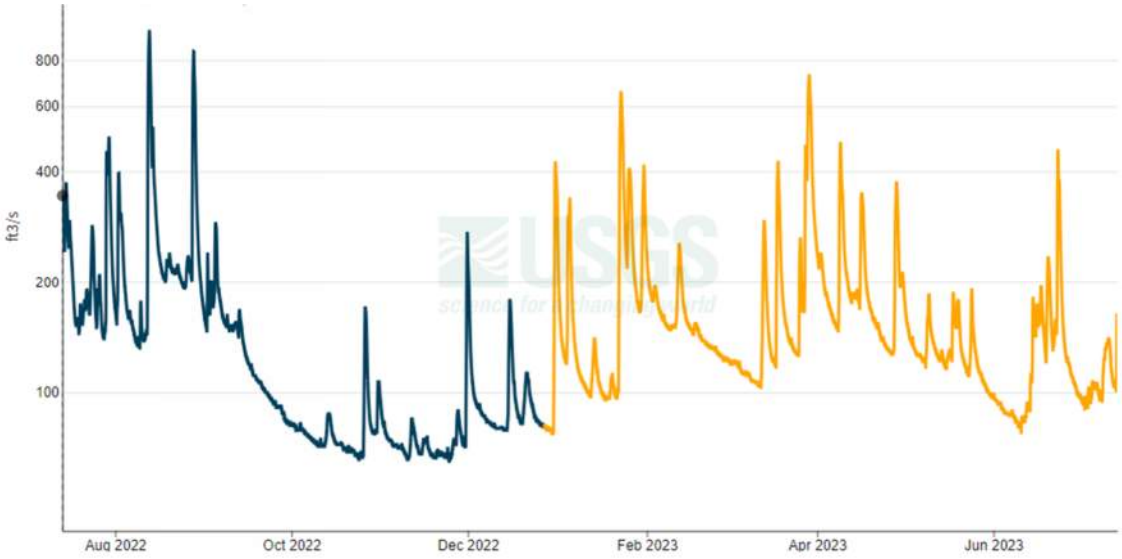

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla. – 02368500
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the

database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030502 and points out the location of the ground water stations in the surroundings. A groundwater-surface layer for the HUC 031401030502 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

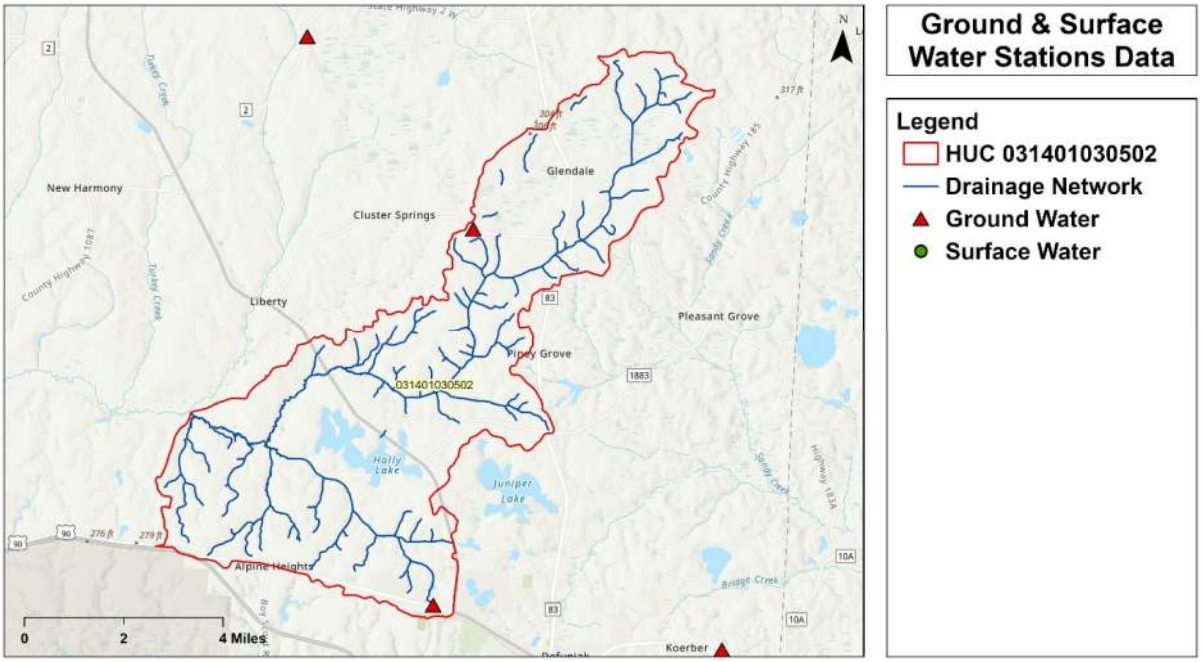

Figure 9. Ground and Surface Water Stations in the HUC 031401030502 sub-watershed, processed by FAU.

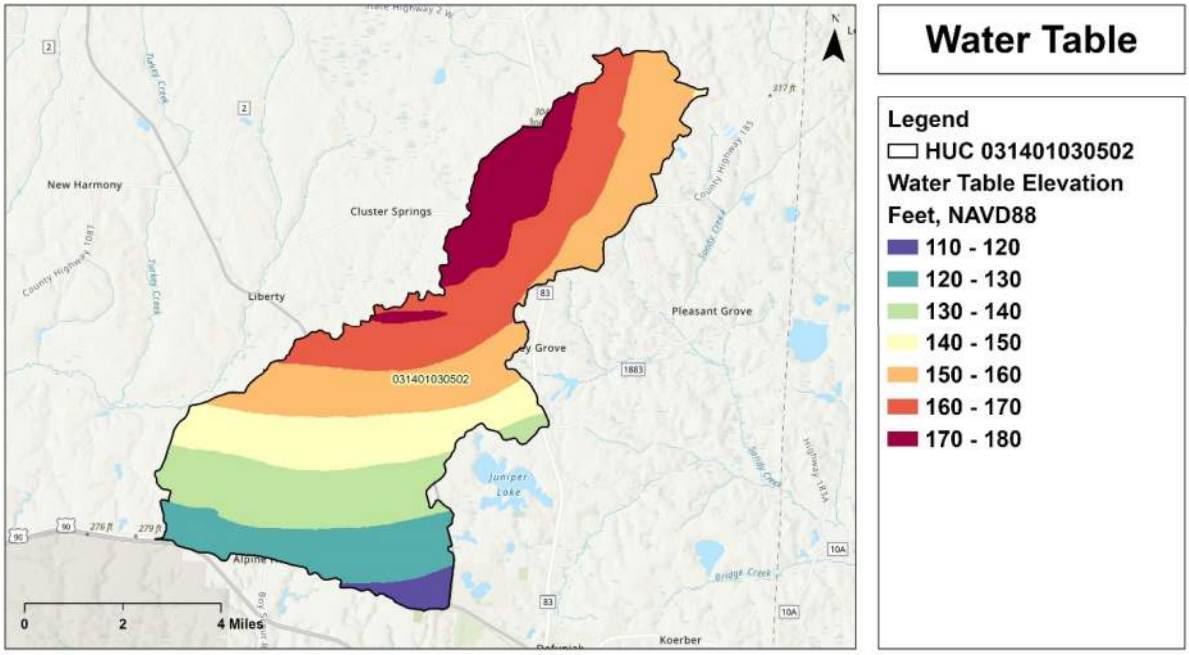

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030502 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

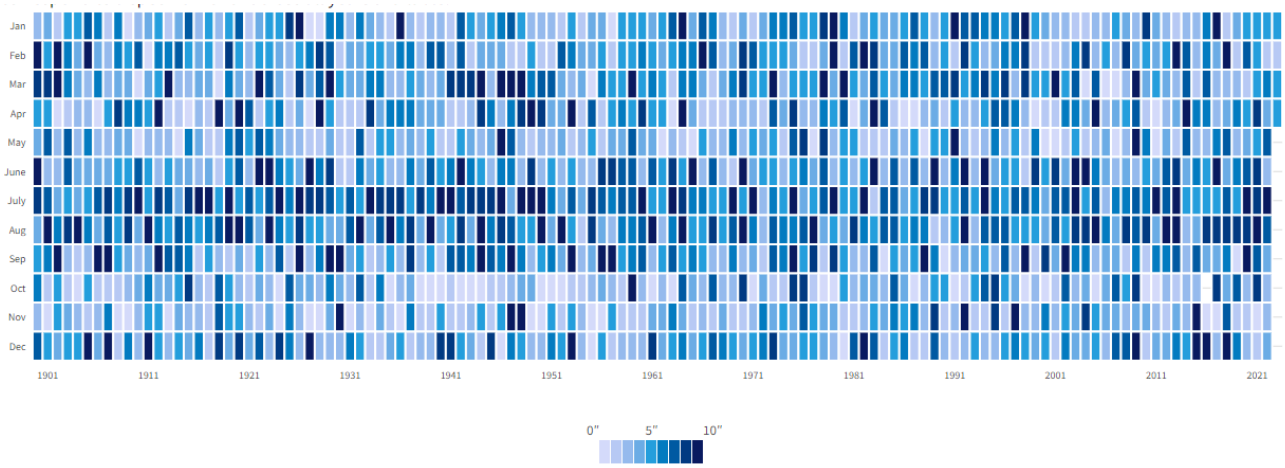

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

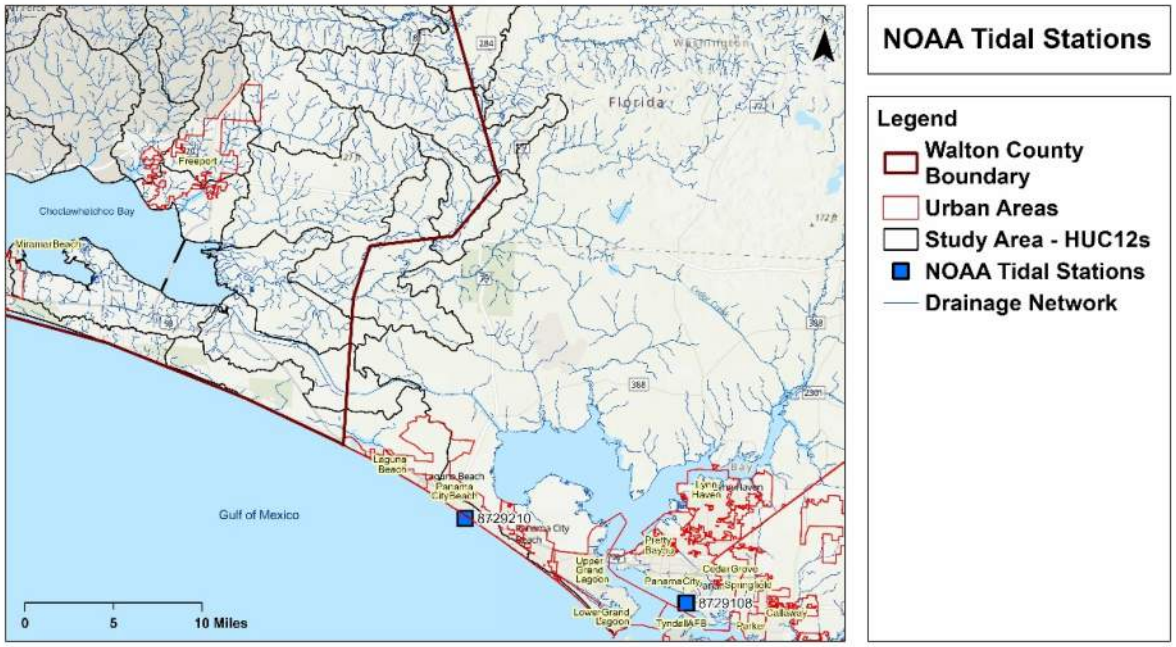

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

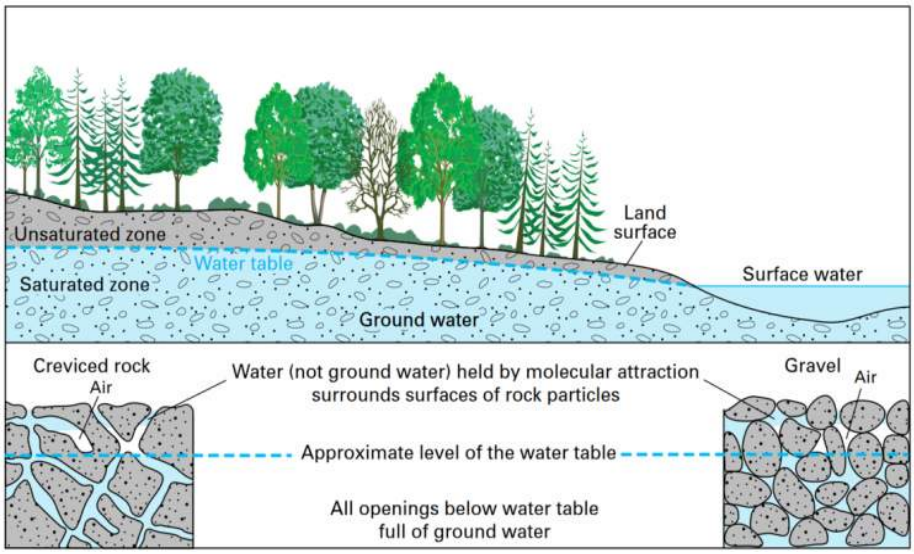

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

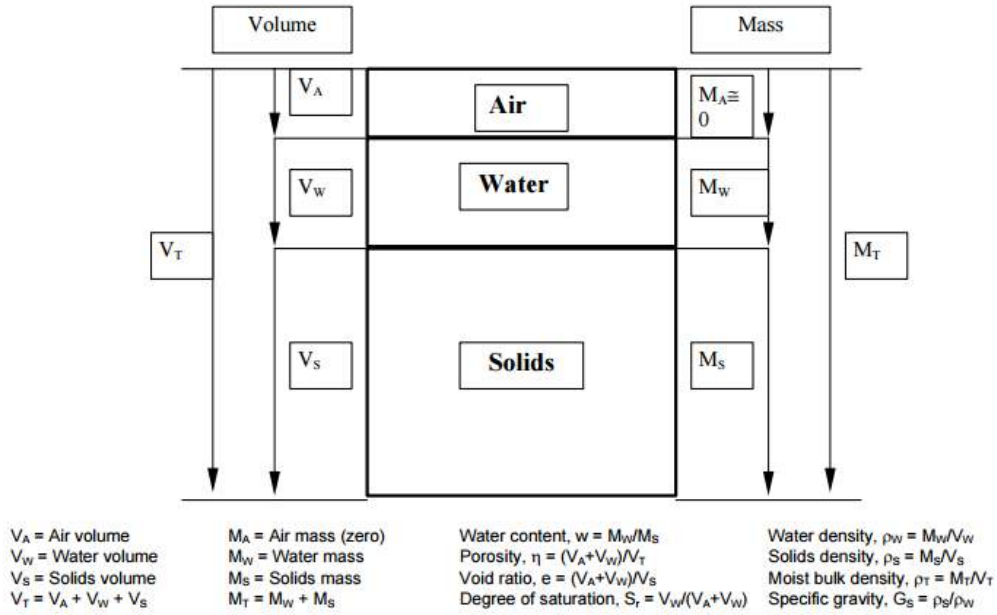

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

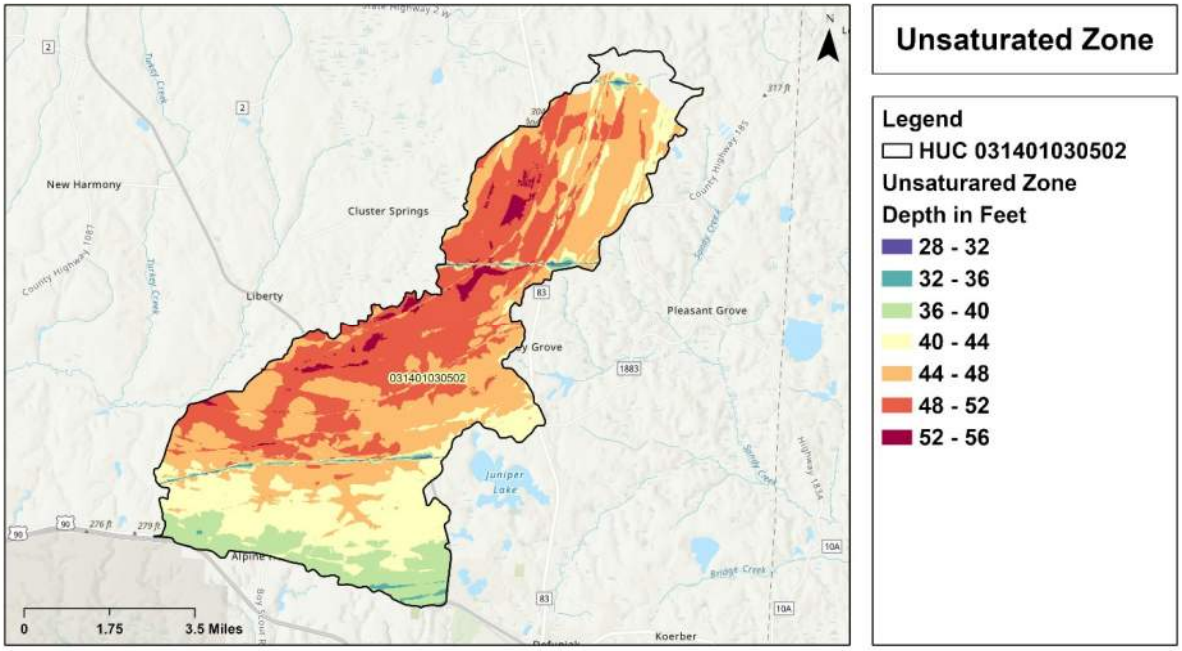

Figure 15. Unsaturated zone map for HUC 031401030502, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. Much of the basin has a medium amount of soil storage capacity, ranging between 30 to 33 inches of capacity left.

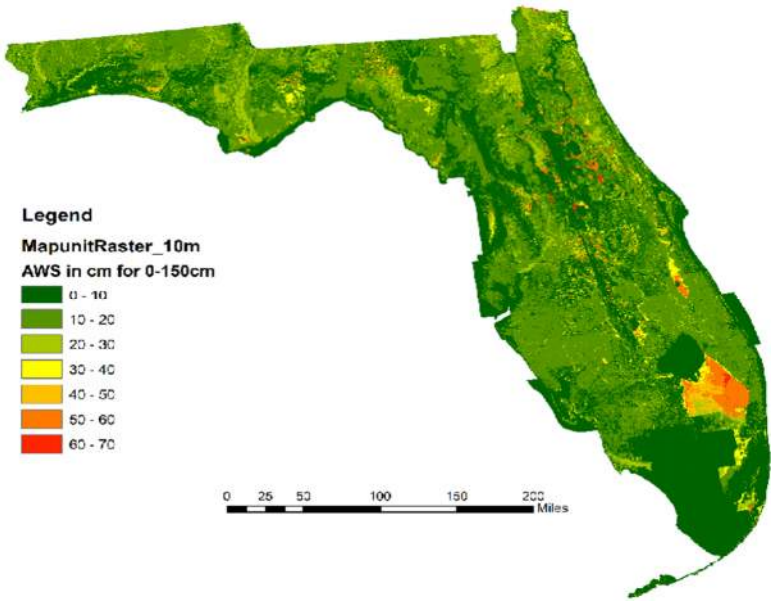

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

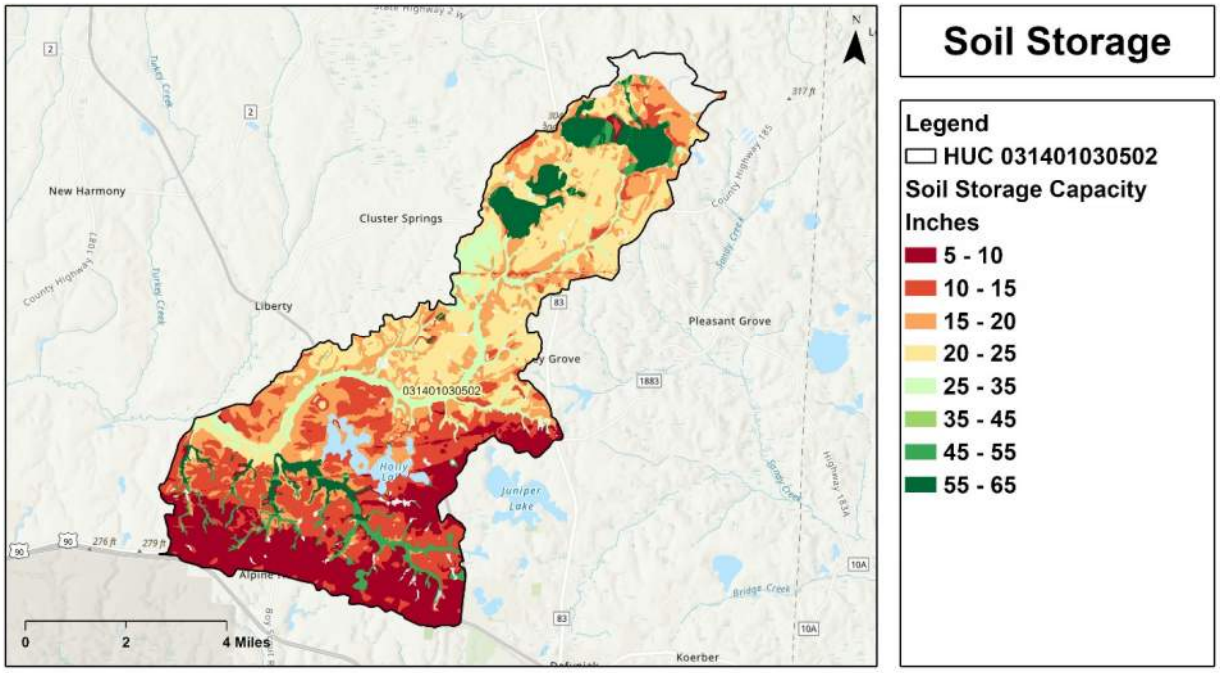

Figure 17. Water storage capacity of soil for the HUC 031401030502, processed by FAU

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

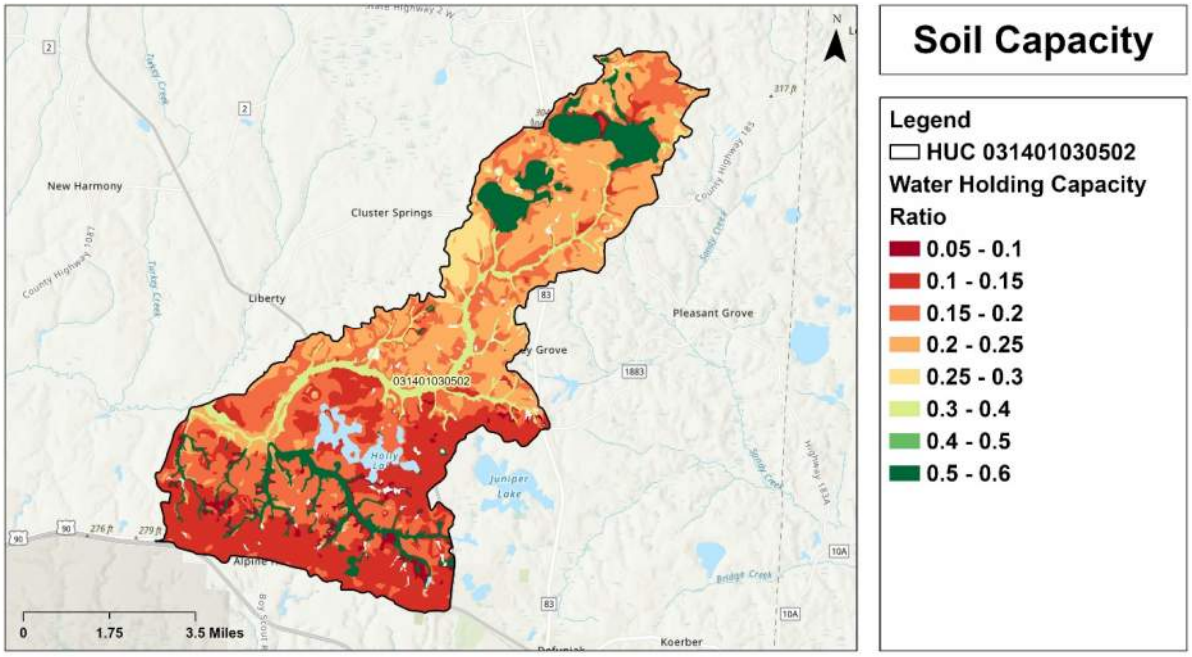

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030502, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

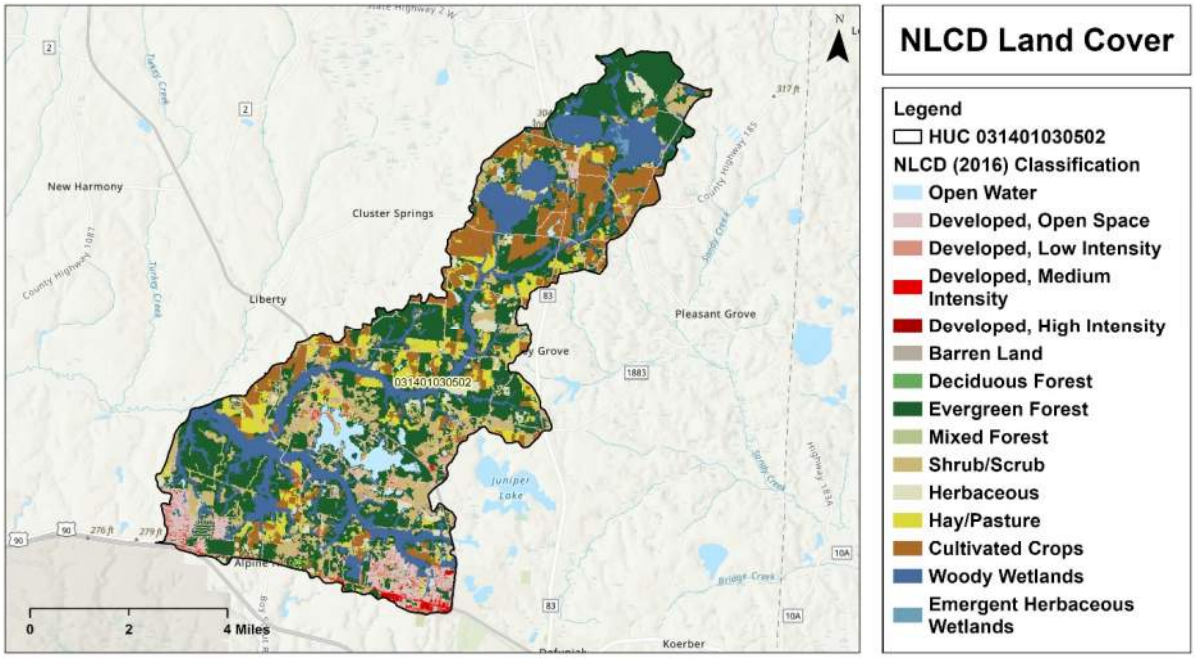

Figure 19. Land use in the HUC 031401030502 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

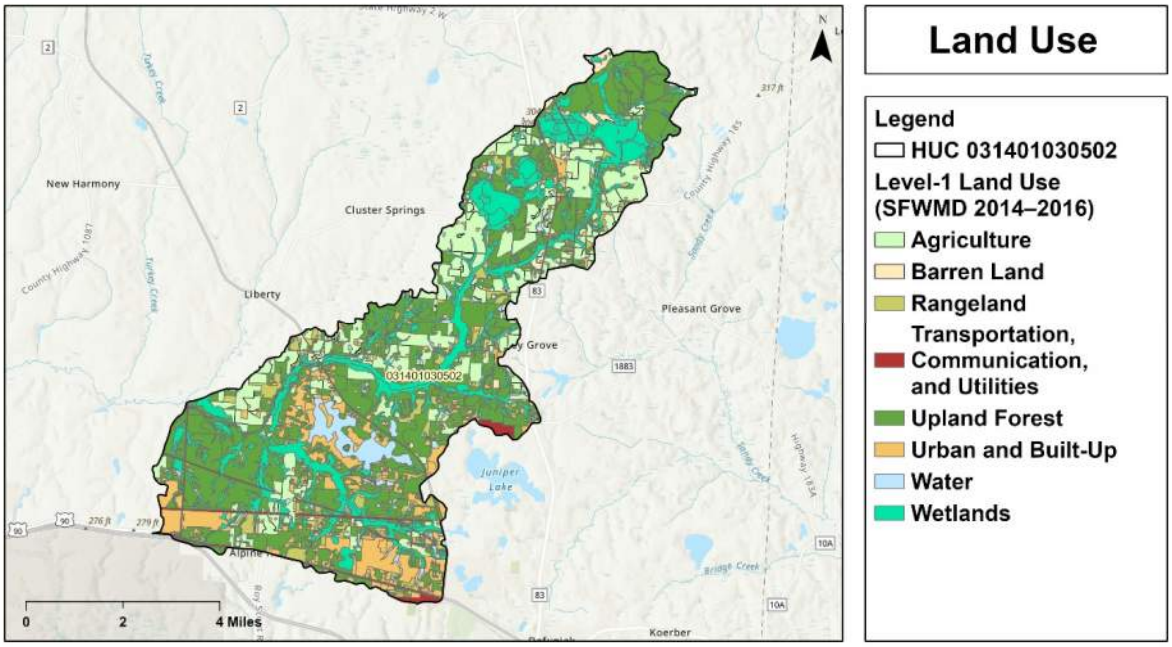

Figure 20. Land use in the HUC 031401030502 (2023 Florida Geographic Data Library (FGDL))), processed by FAU.

In the HUC 031401030502 sub-watershed, the predominant land cover is upland forest, accounting for 37.80% of the area. Agriculture comes in second at 17.17%, followed by wetlands at 15.19%. Developed land constitutes also a good portion, with 11.86% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030502 subwatershed (2023 Florida Geographic Data Library (FGDL))).

Level 1 Land Use Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	6656.86	17.17%
Barren Land	559.50	1.44%
Rangeland	1355.14	3.49%
Transportation, Communication, and Utilities	3717.51	9.59%
Upland Forest	14660.66	37.80%
Urban and Built-Up	4598.01	11.86%

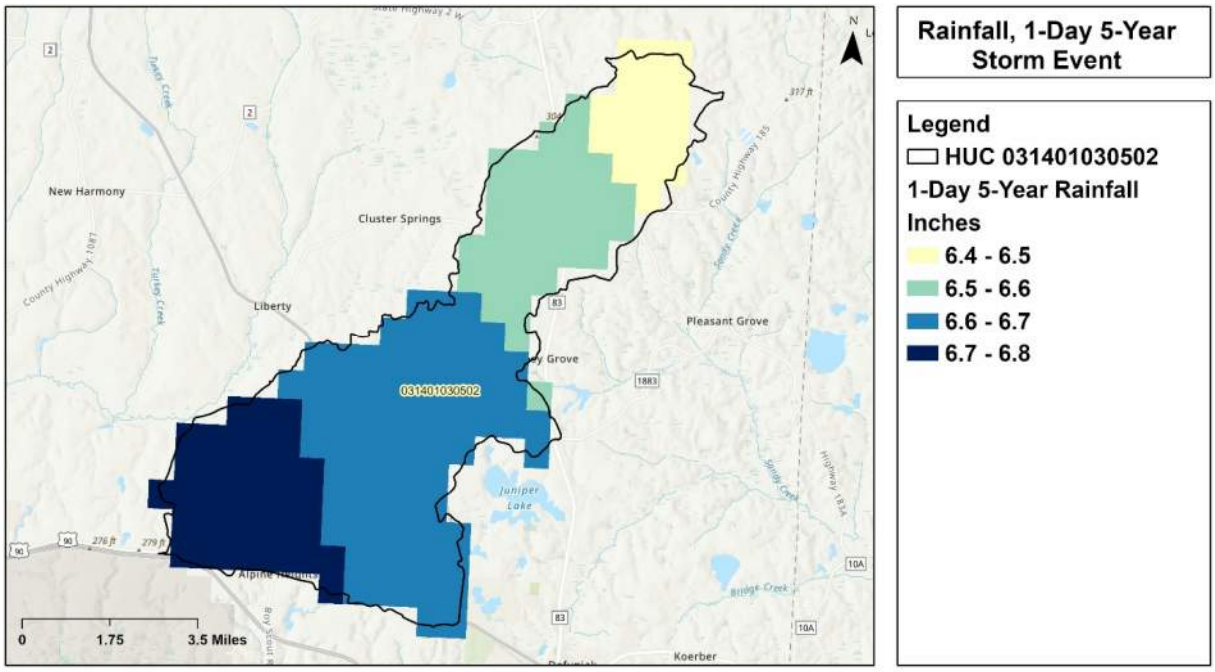

Figure 24. Rainfall distribution map across HUC 031401030502 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 2.5). Added to this will be the water bodies discussed in Section 2.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically

aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

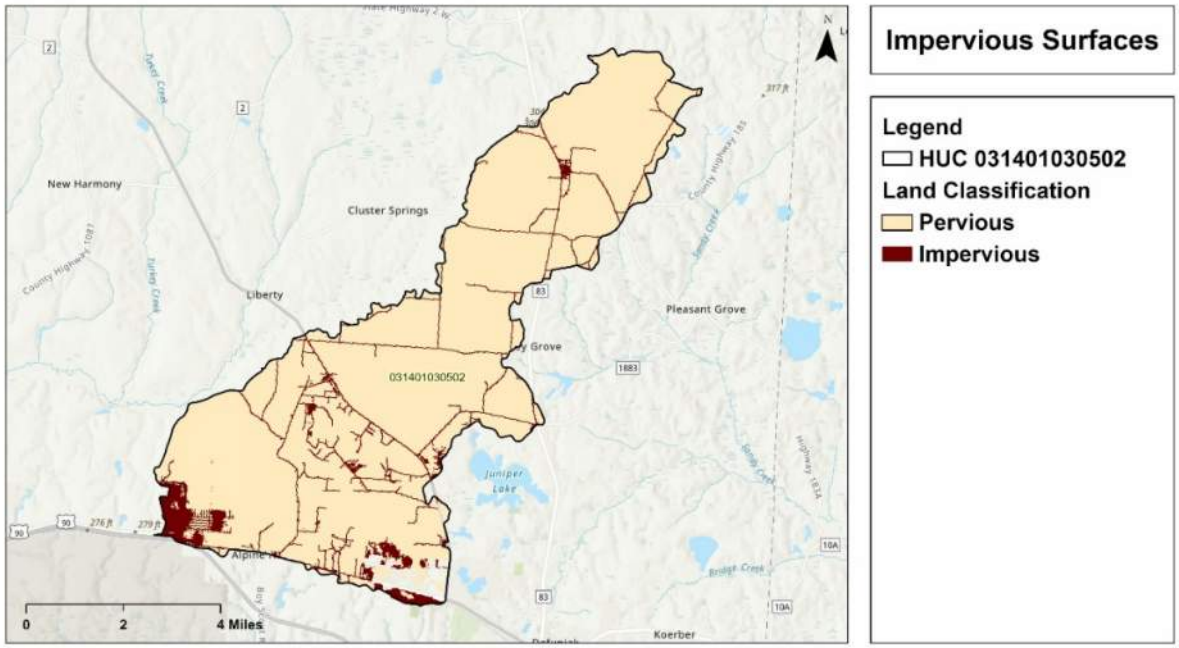

Figure 25. Impervious area map for the HUC 031401030502 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 2.4.

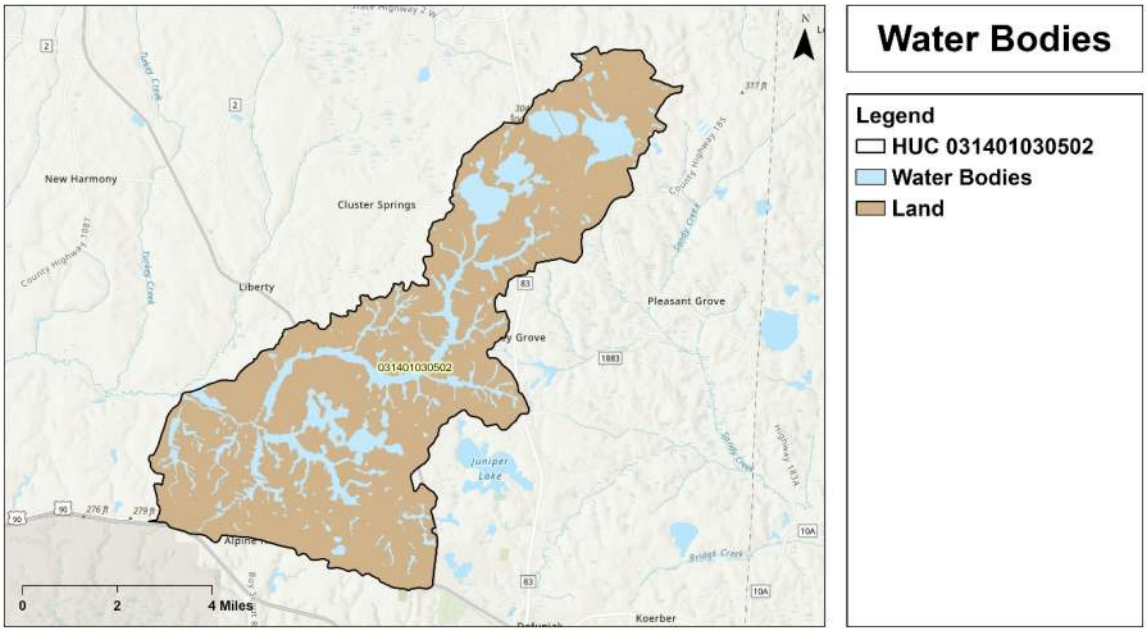

Figure 26. Water bodies map for the HUC 031401030502 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other

waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant

control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

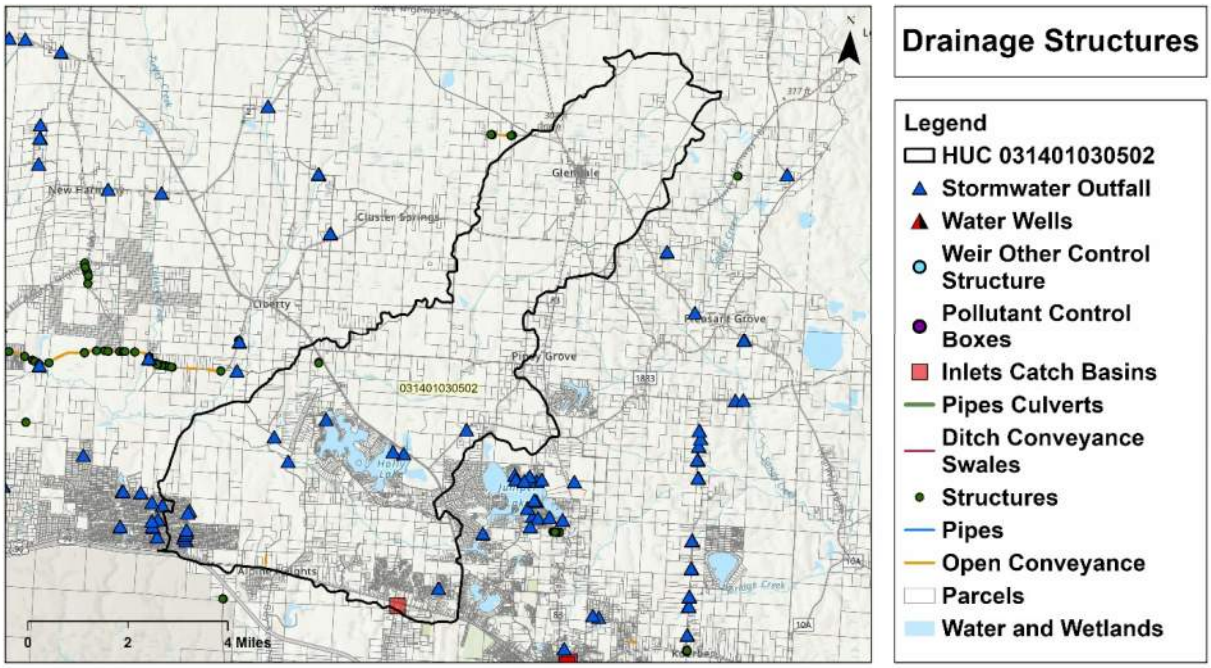

Figure 27. Stormwater Infrastructure for the HUC 031401030502. Processed by FAU.

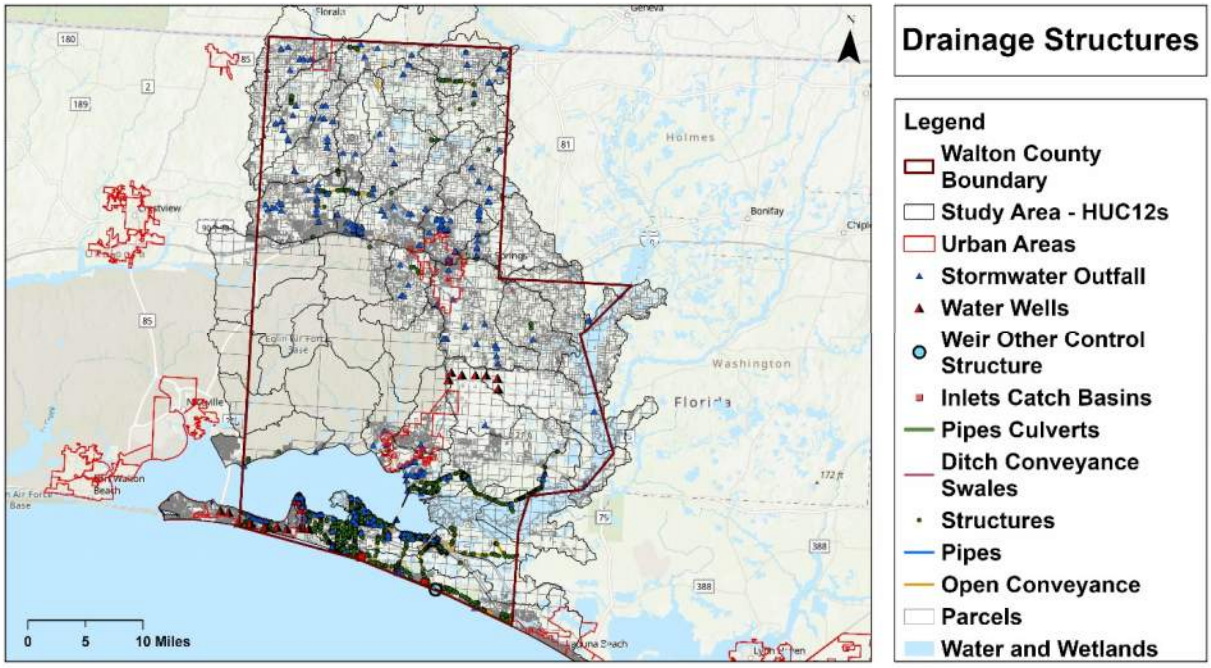

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in Table 5. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapter 1, and analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030502 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the

coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. Figure 29 shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

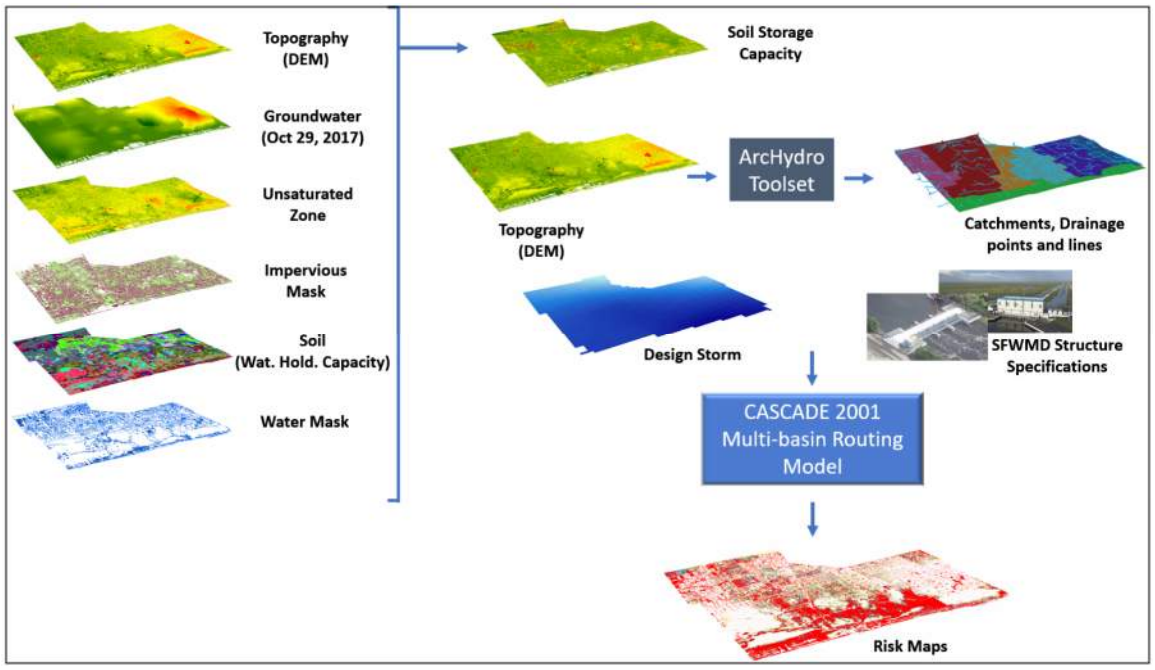

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

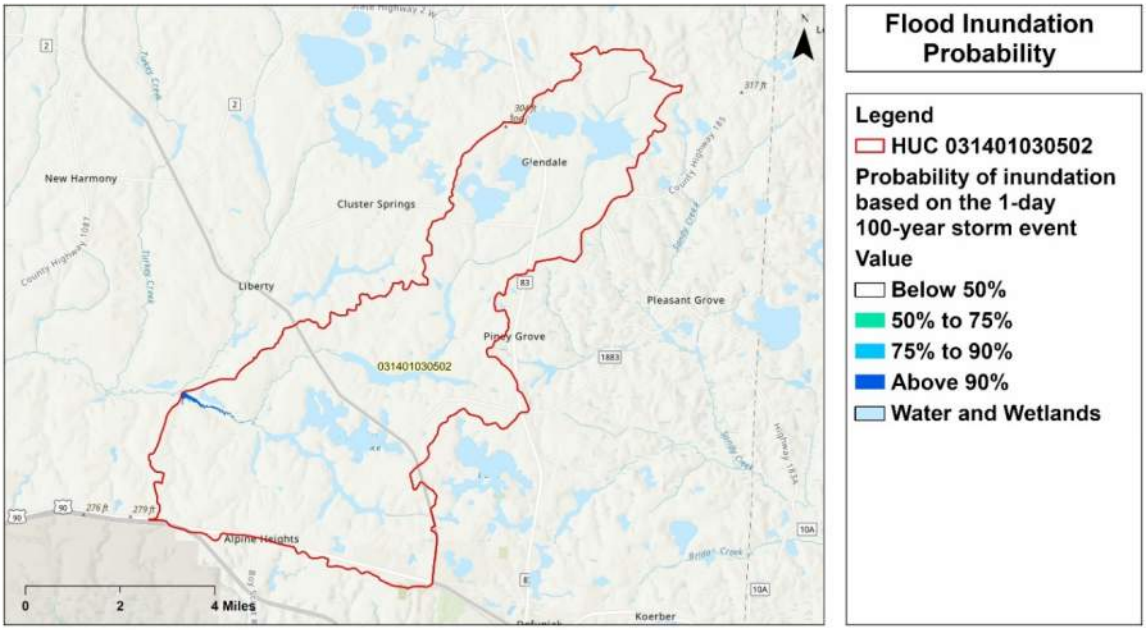

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030502, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is

used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a very small portion of flooding is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 1.9% of the HUC total area or 0.56 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 1.9% of the HUC's total area, or 0.56 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 1.9% of the HUC's total area, or 0.56 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 1.9% of the HUC's total area, or 0.56 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030502 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	28.94	0.56	98.1%	1.9%
1-day 100-year	28.94	0.56	98.1%	1.9%
1-day 10-year	28.94	0.56	98.1%	1.9%
1-day 5-year	28.94	0.56	98.1%	1.9%

Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations.
Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6
1	Single Family Residential	5

103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.**depict the HUC 031401030502 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.**is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.**illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

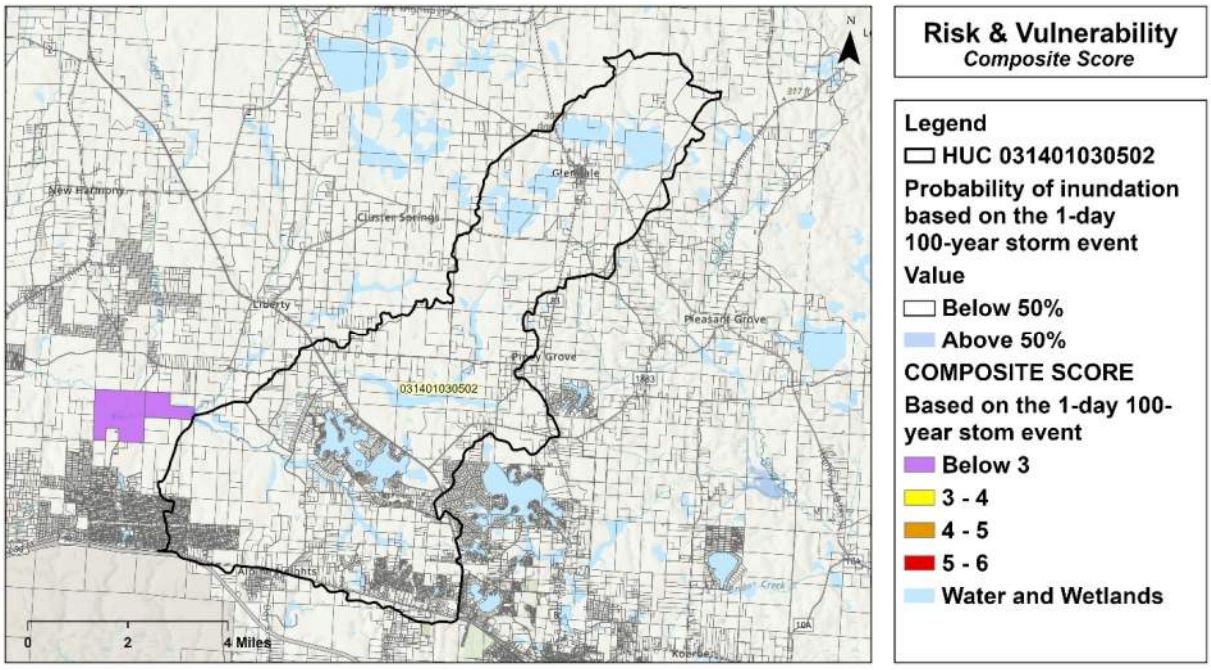

Figure 38. HUC 031401030502 sub-watershed Composite Score Risk map, calculation based on 1-day 100-year storm event. Processed by FAU.

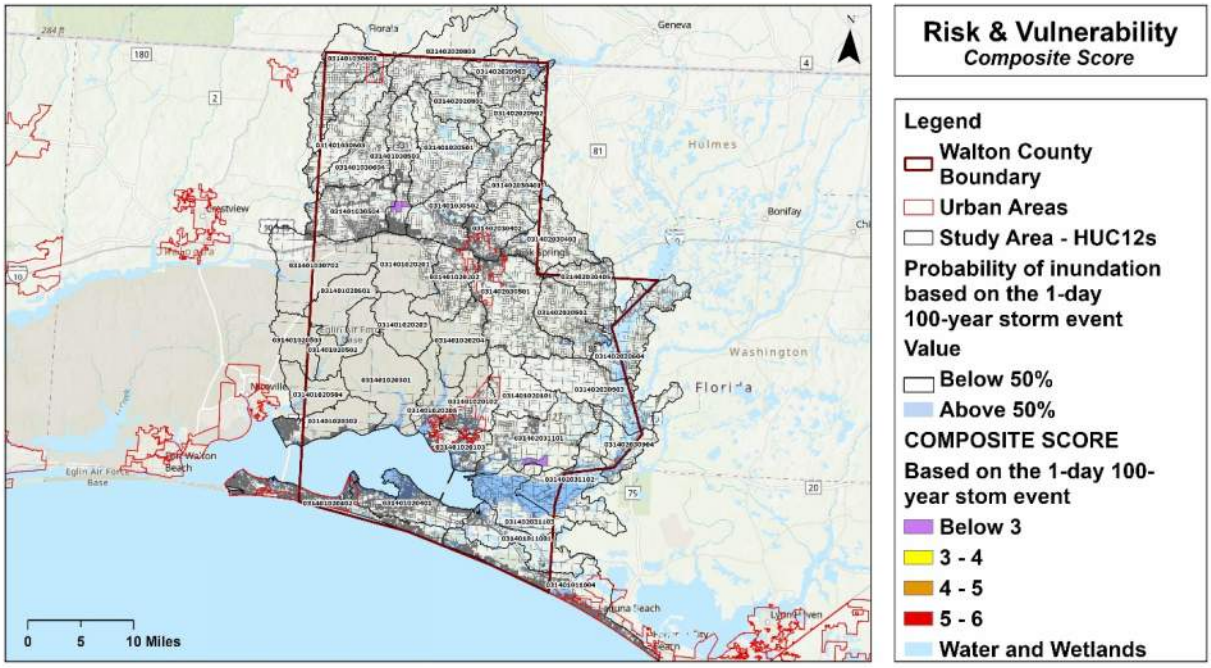

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030502. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030502. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030502	28950.54
All of the 1-day 100-year storm event inundation	**45.29**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	45.29
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	45.29

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not**

found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

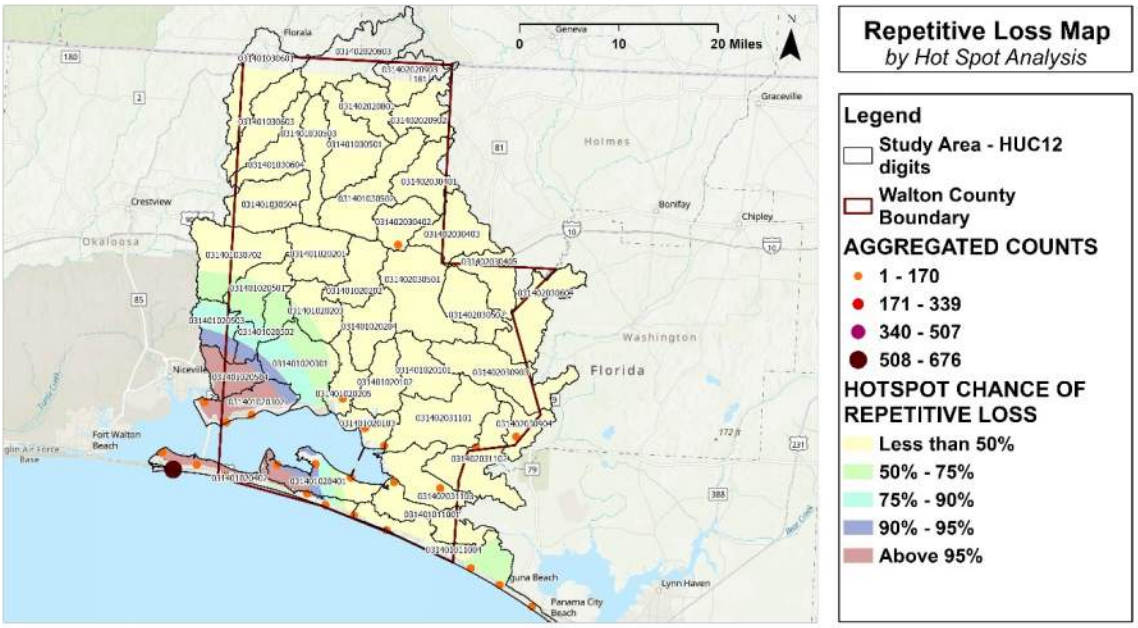

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5. Priority Projects

Although there are a few parcels falling within classification tier 1 to 3, and a good amount of parcels falling within tiers 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding in the area is minor and not alarming. Consequently, when considering the composite score, it notable that there is no critical facilities situated within the flooding zone, indicating no necessity for priority projects intervention within the basin.

More detail about flood solutions are described in the community plan and in Section 5.5 where drilldown to specific neighborhoods is outlined.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (Figure 1). Figure 2 shows Walton County Drainage Network and the location of urban areas (cities and towns). In Figure 3, the HUC-12 digits (031401030503) is highlighted among all the HUCs to help identifying its location. (Figure 3).

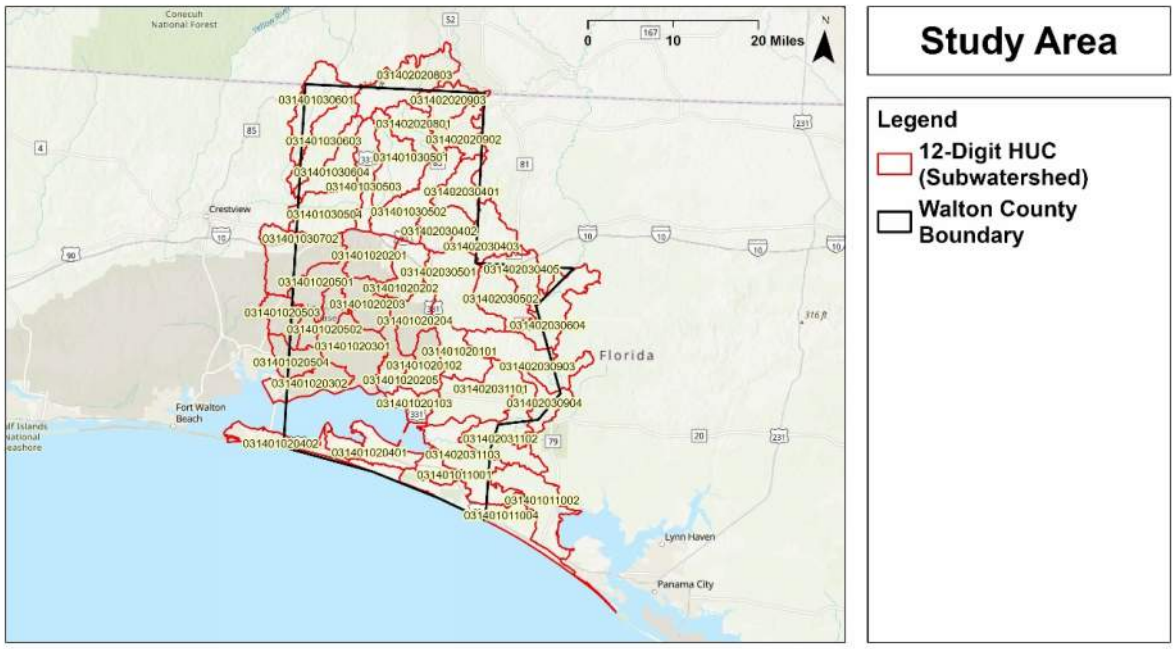

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

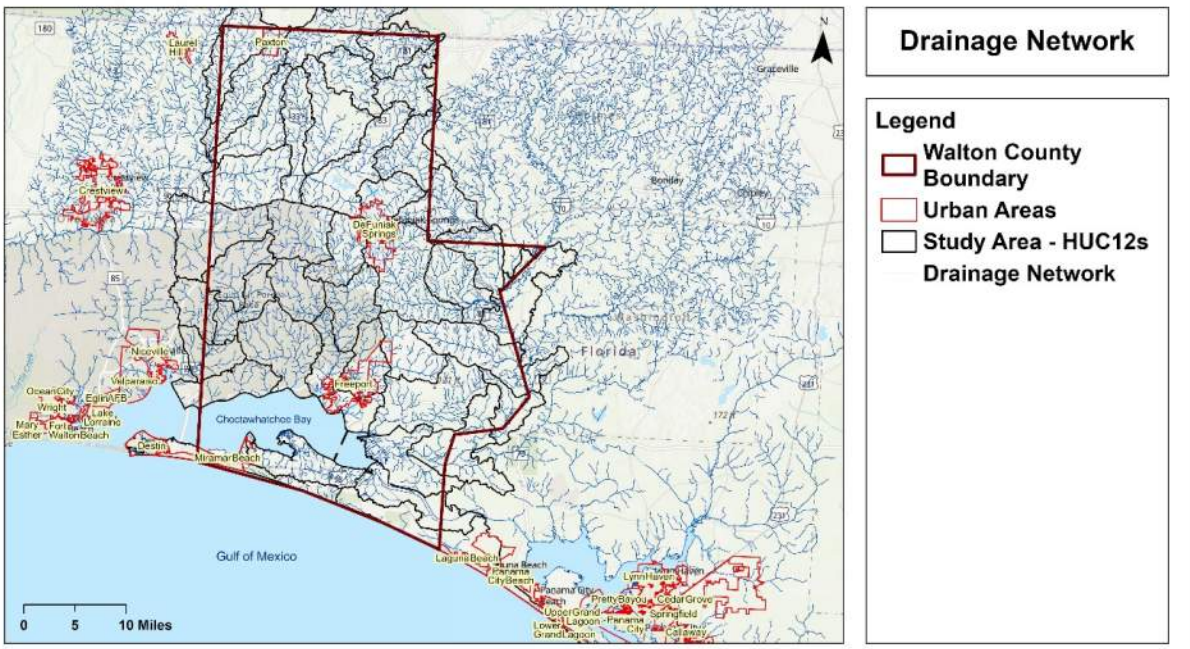

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

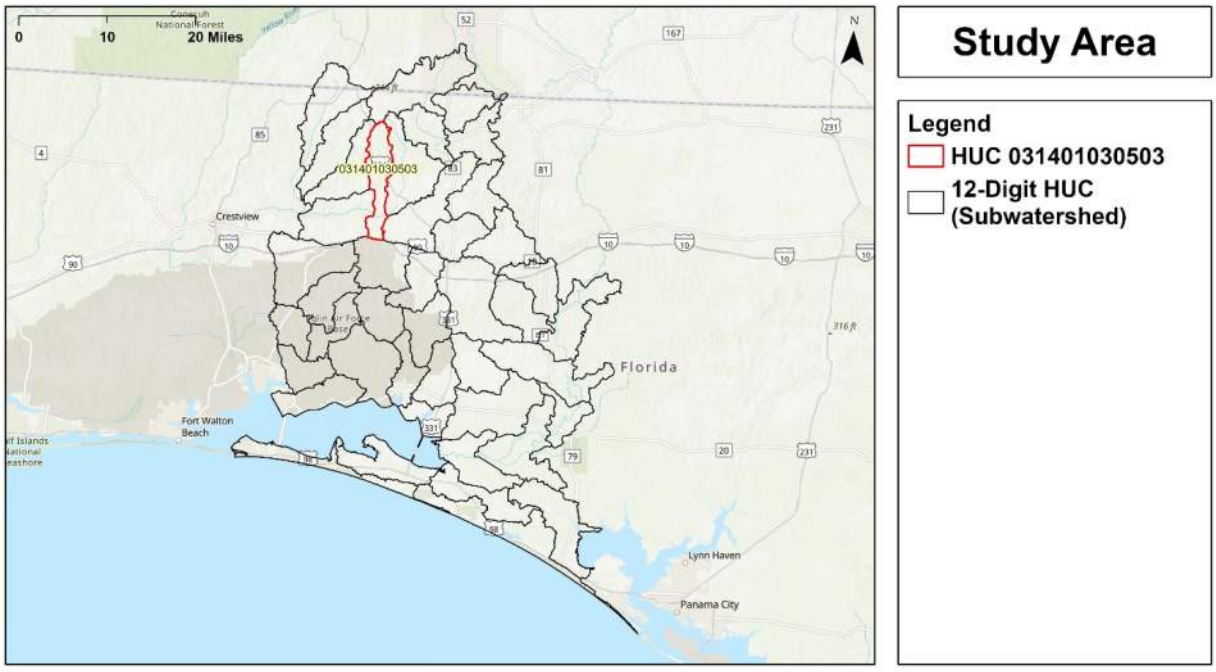

Figure 3. HUC 031401030503 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

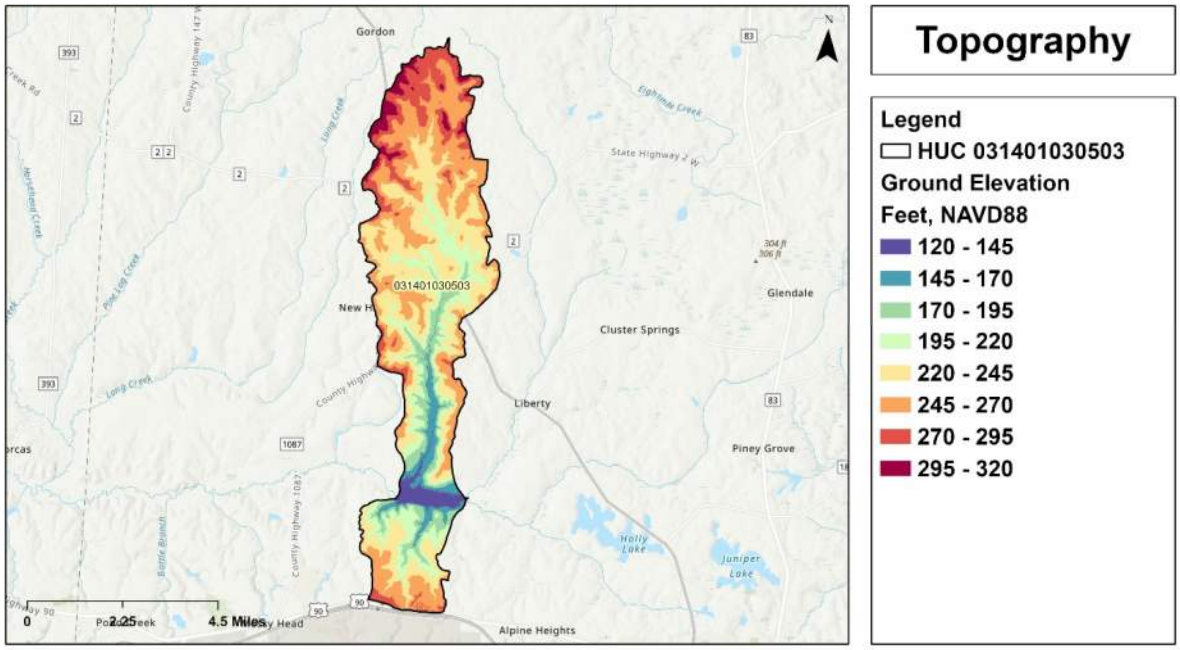

Figure 4. Topographic map of the HUC 031401030503 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030503 sub-watershed is shown in **Error! Reference source not found.**.

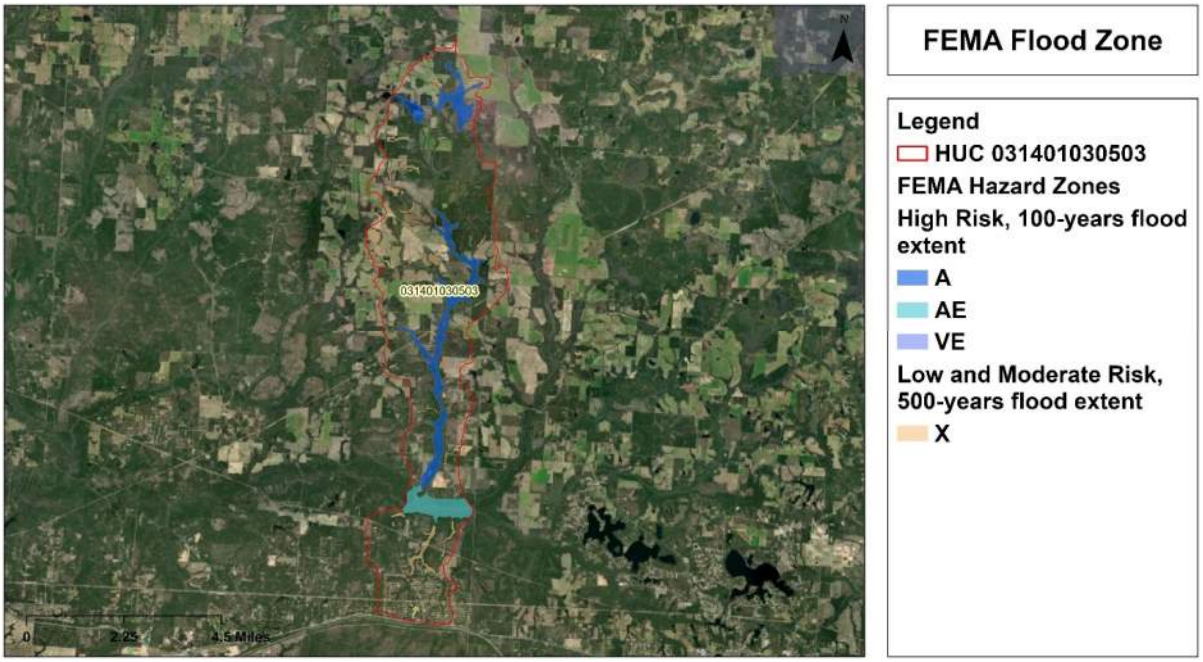

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030503 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination

between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030503 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

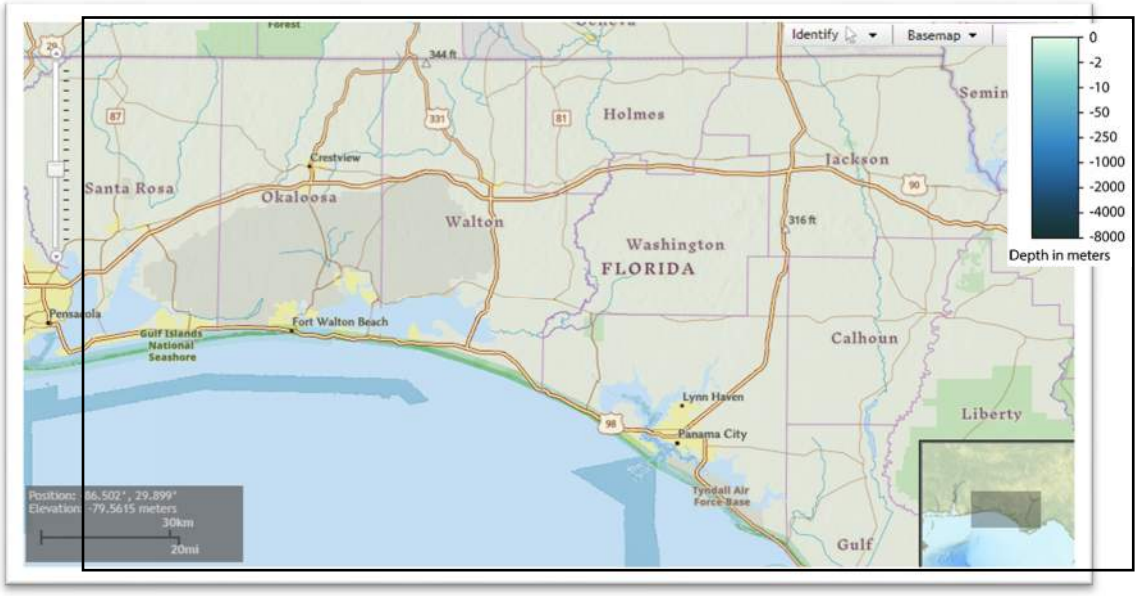

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle. Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

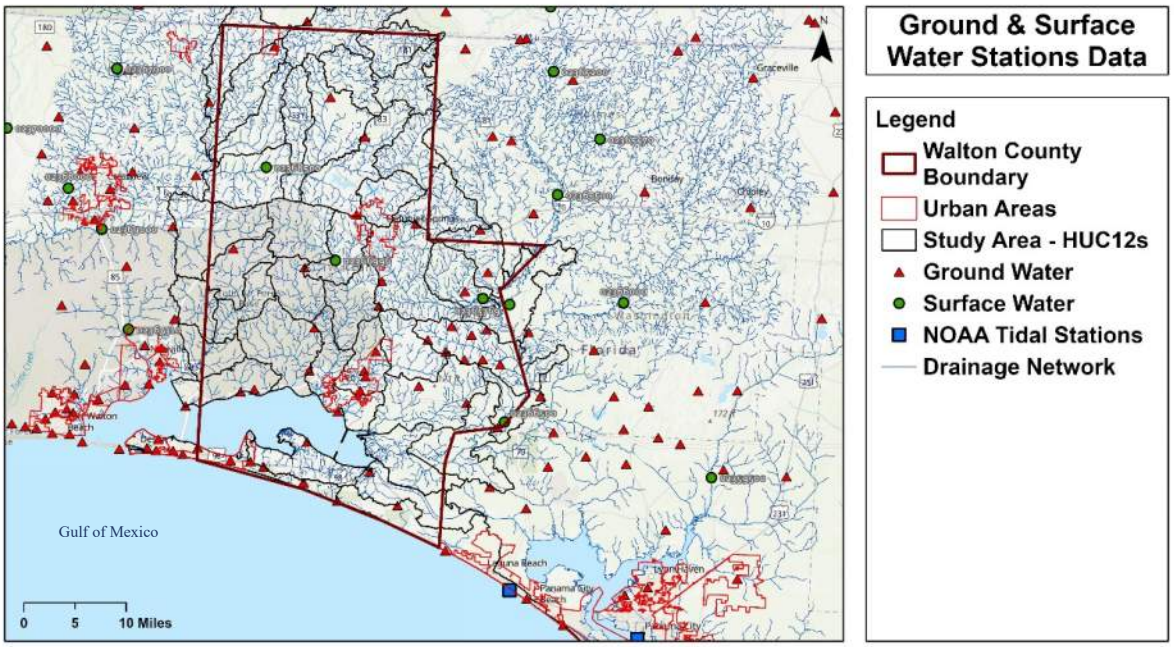

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The major water bodies in the HUC 031401030503 sub-watershed include:

- Shoal River
- Turkey Creek
- Mil Dam Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030503, which is USGS 02368500 Shoal River.

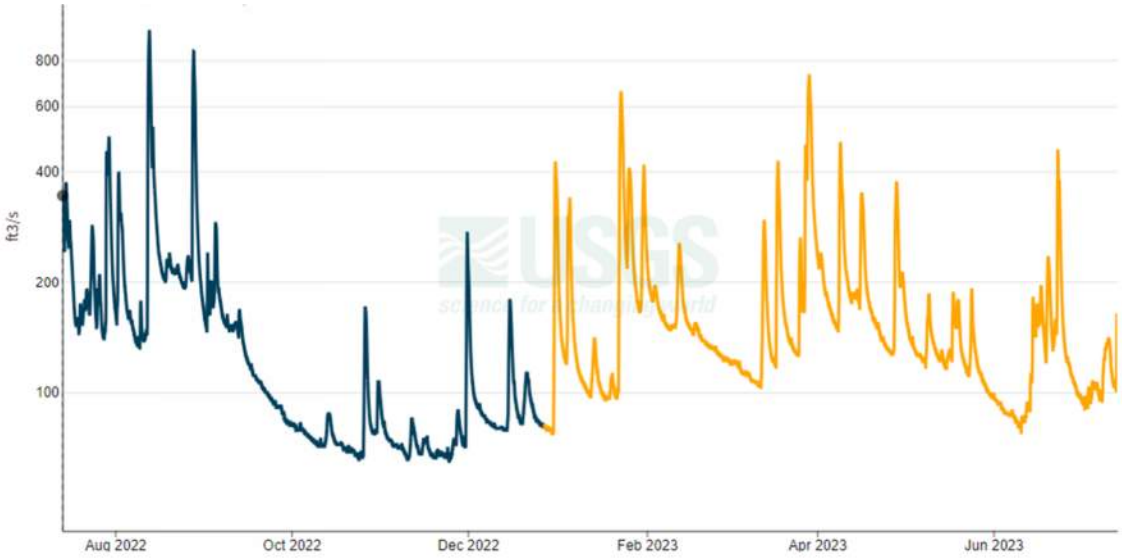

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99^{th}- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98^{th} - 100^{th} percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030503 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401030503 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

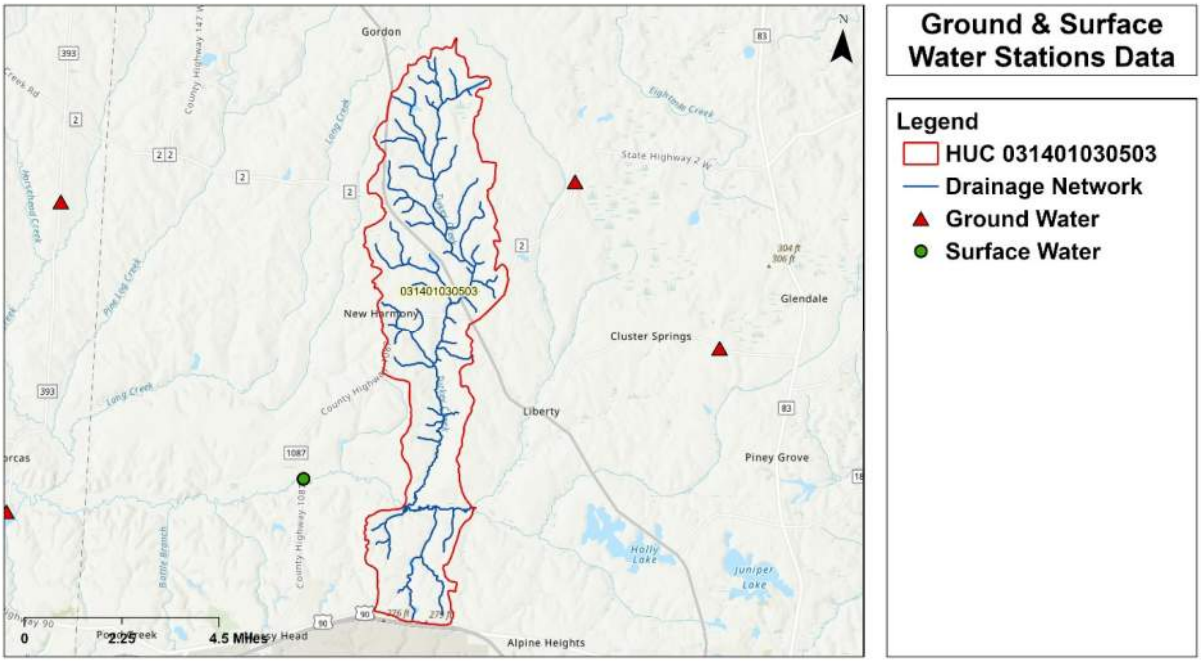

Figure 9. Ground and Surface Water Stations in the HUC 031401030503 sub-watershed, processed by FAU.

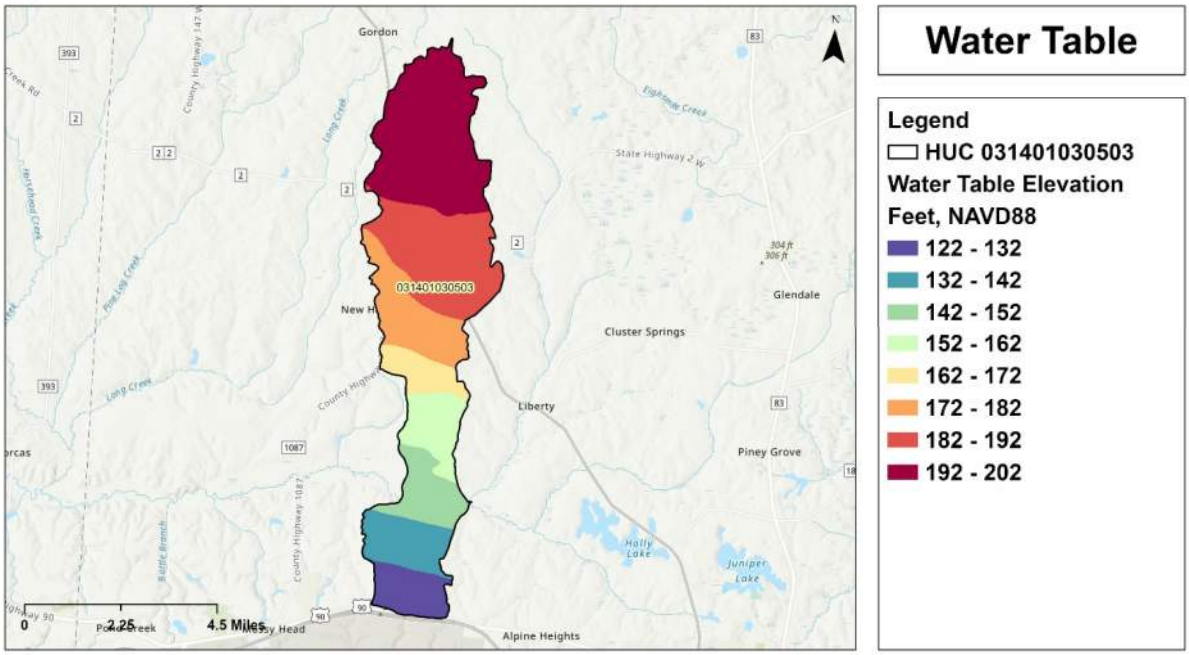

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030503 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

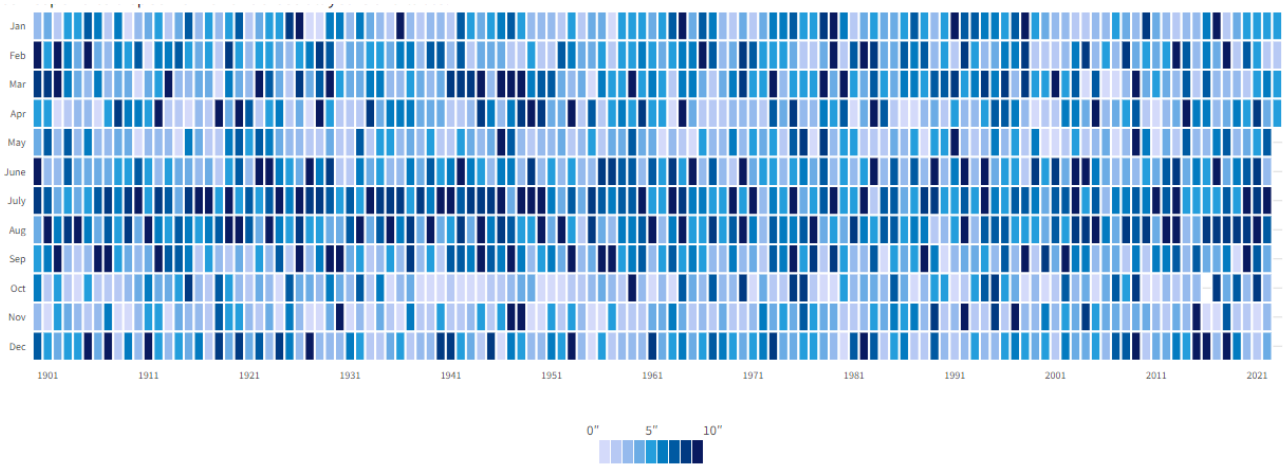

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information.
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

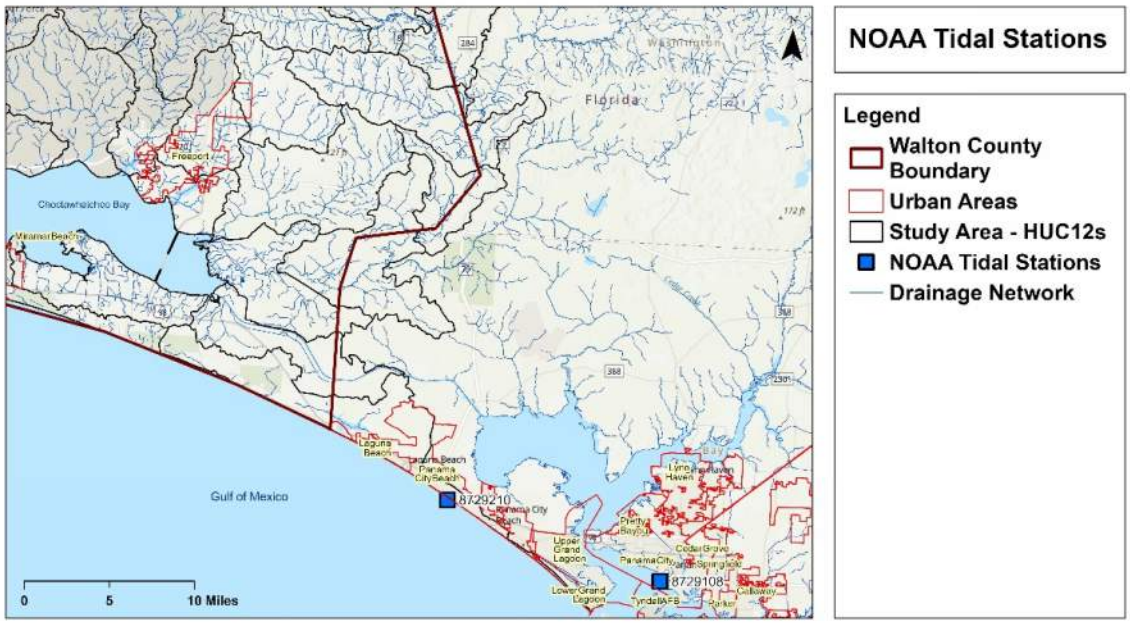

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

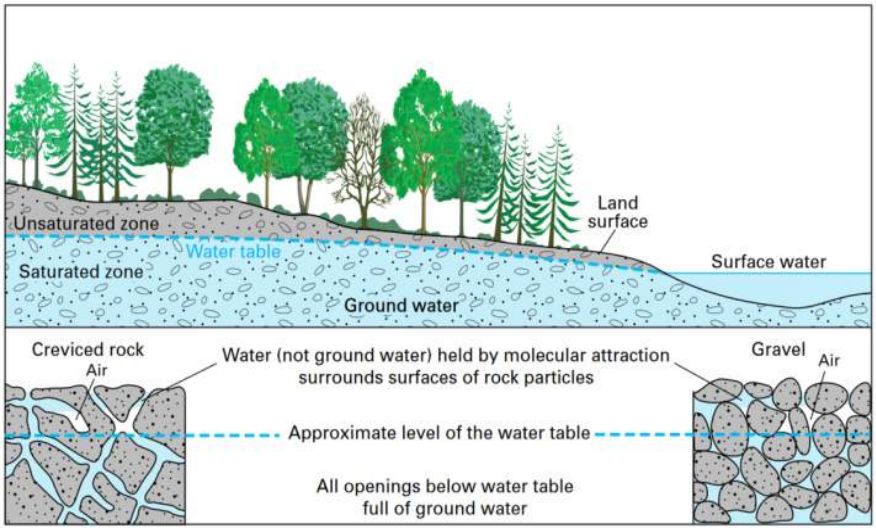

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

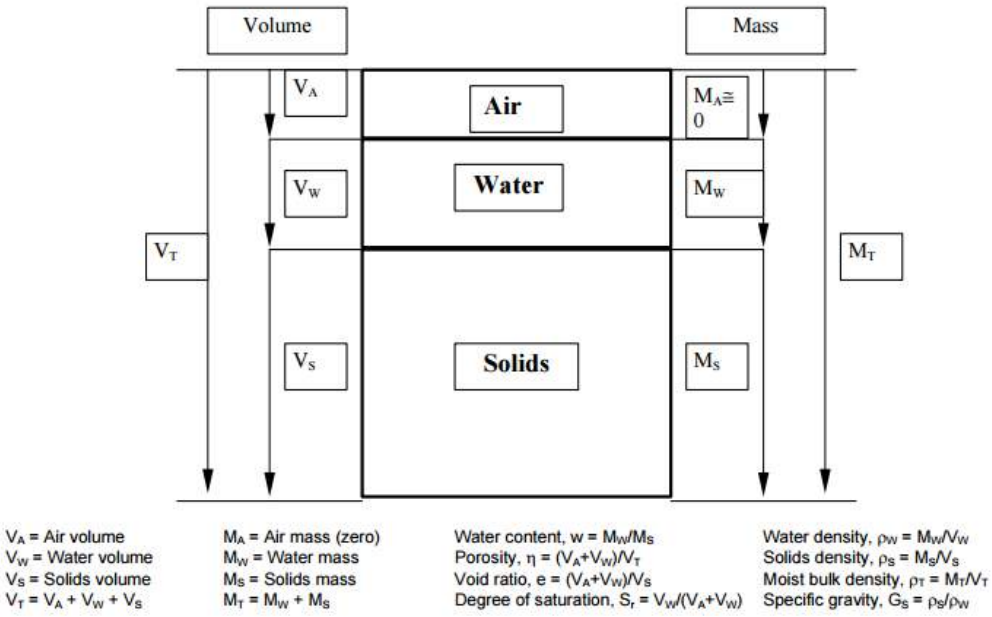

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

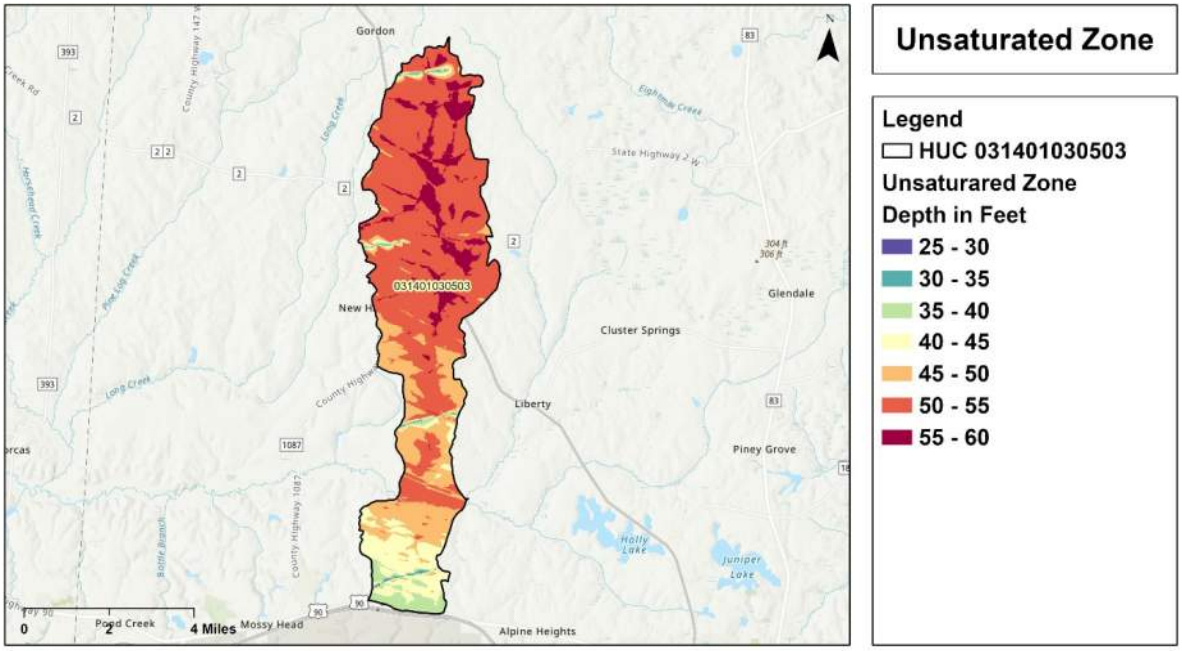

Figure 15 Unsaturated zone map for HUC 031401030503, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. Much of the basin has a great amount of soil storage capacity, ranging between 40 to 60 inches of capacity left.

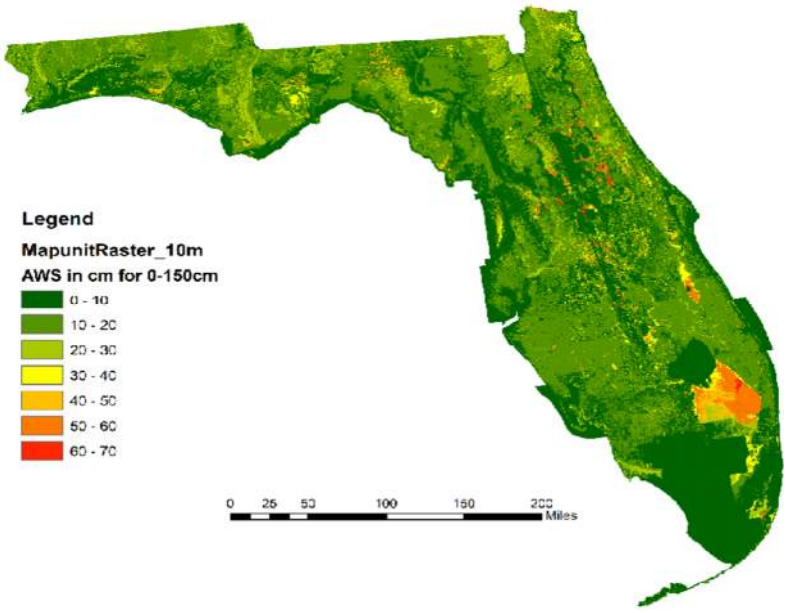

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

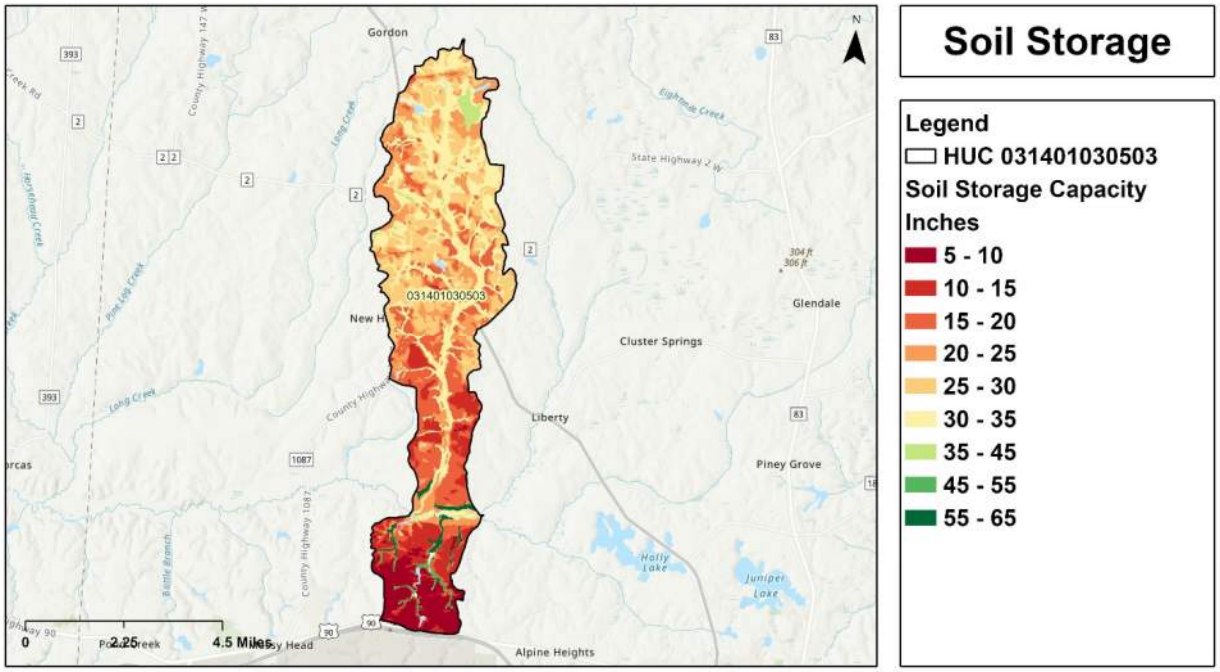

Figure 17. Water storage capacity of soil for the HUC 031401030503, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

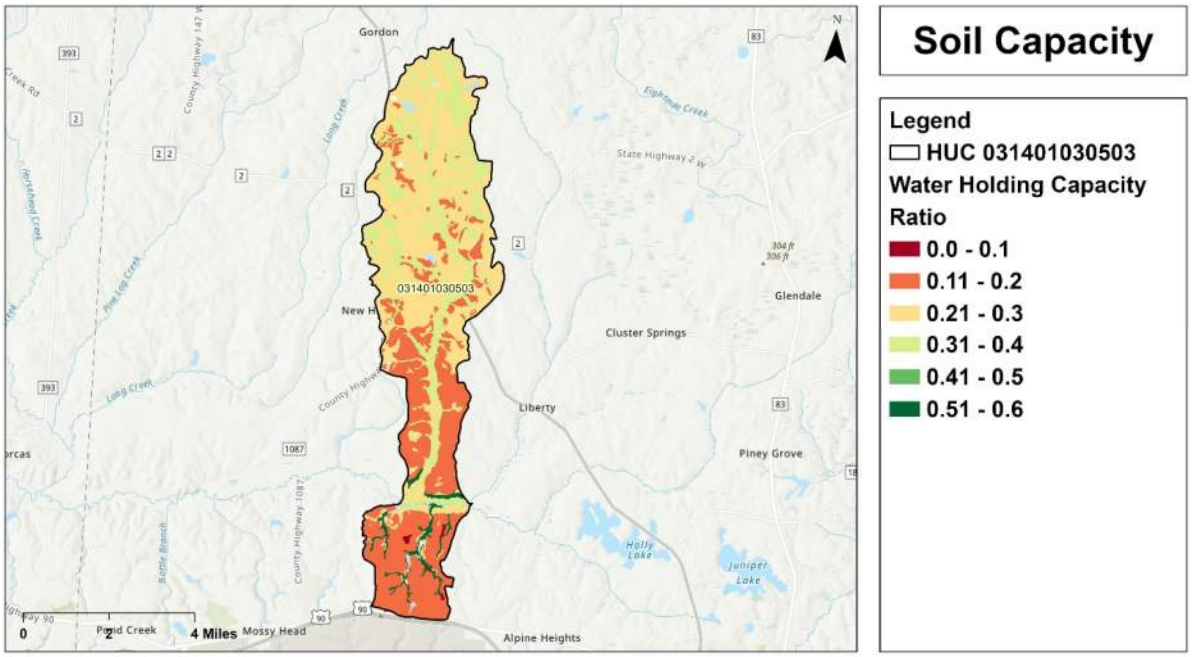

Figure 18: Water Holding Capacity (ratio) for the HUC 031401030503, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

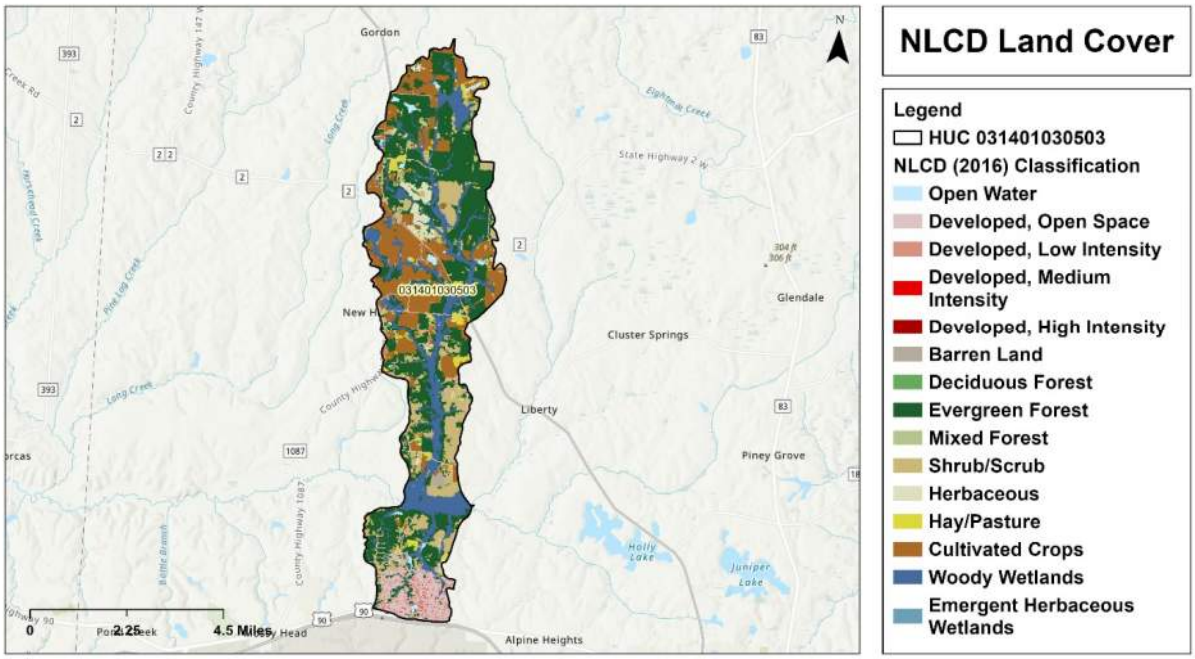

Figure 19. Land use in the HUC 031401030503 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps were used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

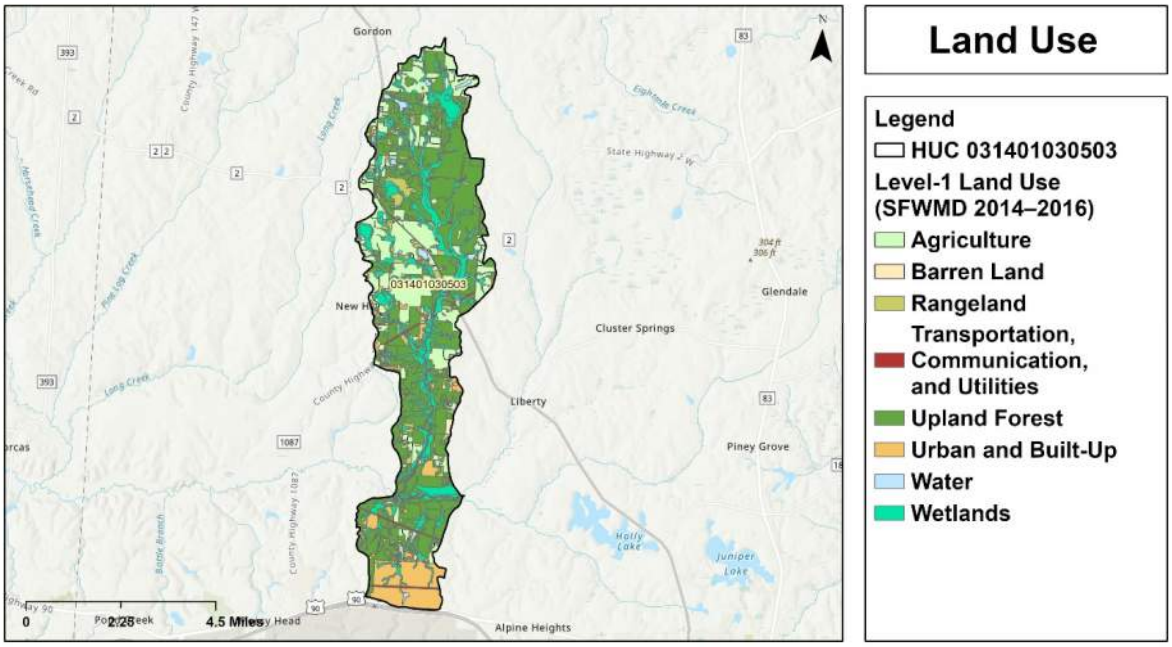

Figure 20. Land use in the HUC 031401030503 (2023 Florida Geographic Data Library (FGDL))database), processed by FAU.

In the HUC 031401030503 sub-watershed, mostly of the area is upland forest, with 40.90%. The second place is agriculture with 21.55%. There is no much developed land in the HUC – only 6.98% is urban and built-up, but there is a considerable amount of land being used for Transportation, Communication, and Utilities (12.92%), which is unusual, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030503 subwatershed (2023 Florida Geographic Data Library (FGDL))).

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	5680.73	21.55%
Barren Land	100.31	0.38%
Rangeland	557.81	2.12%
Transportation, Communication, and Utilities	3405.53	12.92%
Upland Forest	10781.12	40.90%
Urban and Built-Up	1839.39	6.98%
Water	558.63	2.12%
Wetlands	3434.03	13.03%
Grand Total:	**26357.54**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

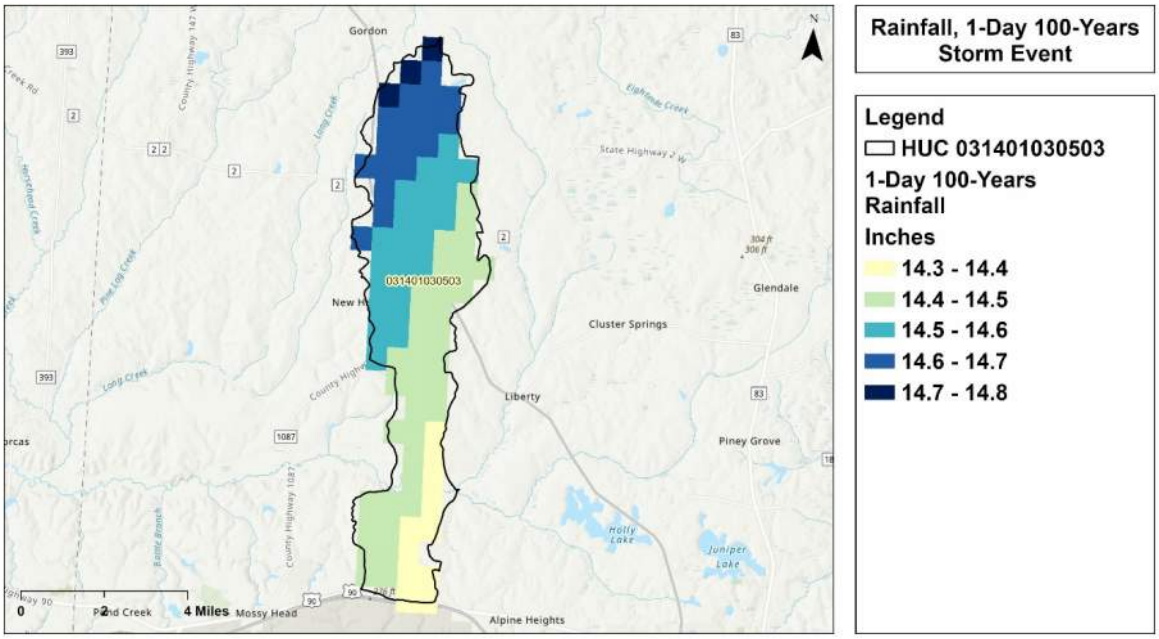

Figure 22. Rainfall distribution map across HUC 031401030503 sub-watershed, for 1-day 100-year storm event, processed by FAU.

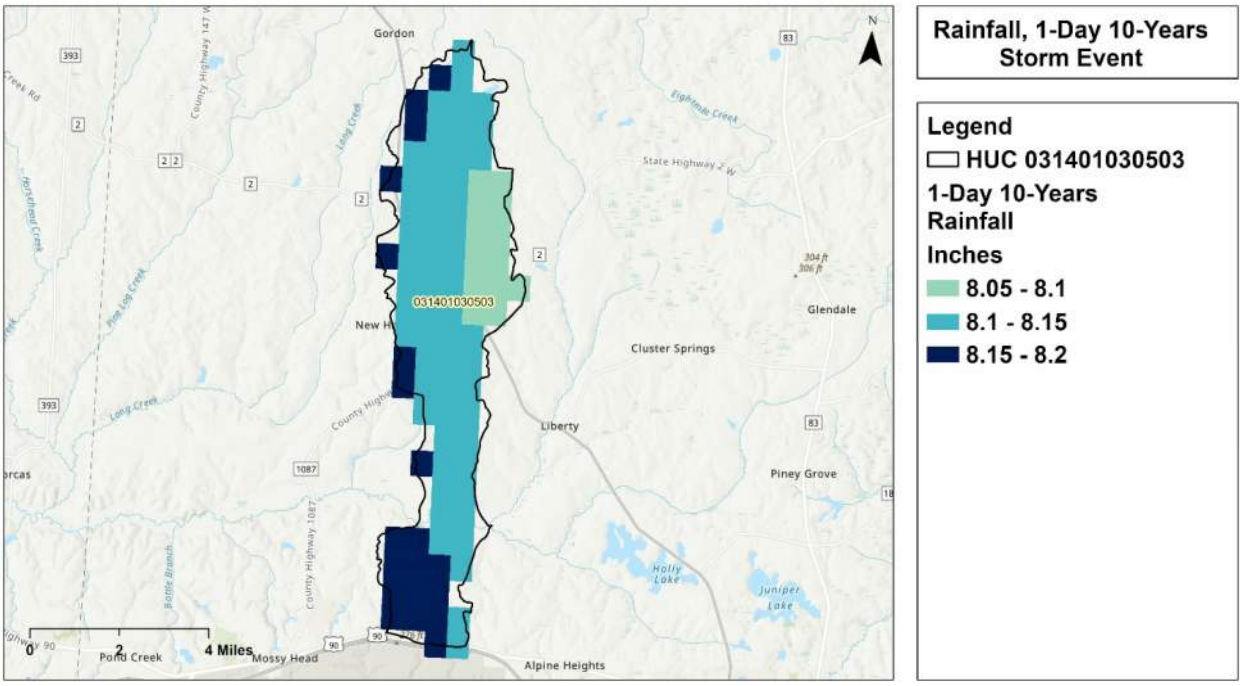

Figure 23. Rainfall distribution map across HUC 031401030503 sub-watershed, for 1-day 10-year storm event, processed by FAU.

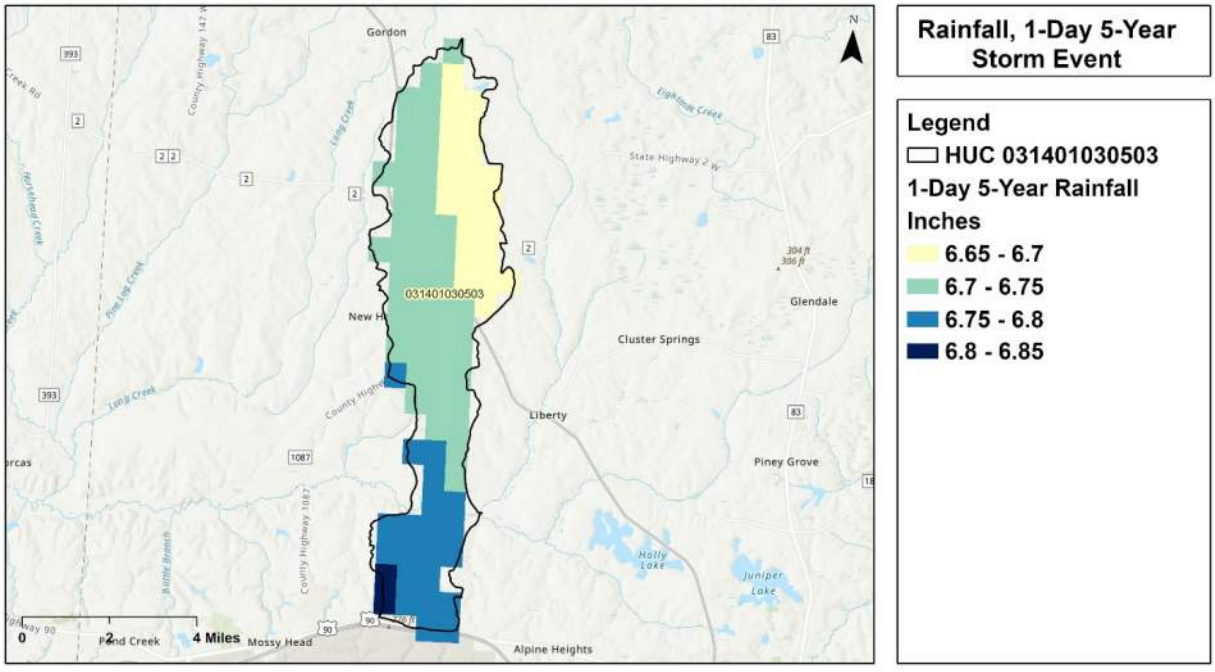

Figure 24. Rainfall distribution map across HUC 031401030503 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

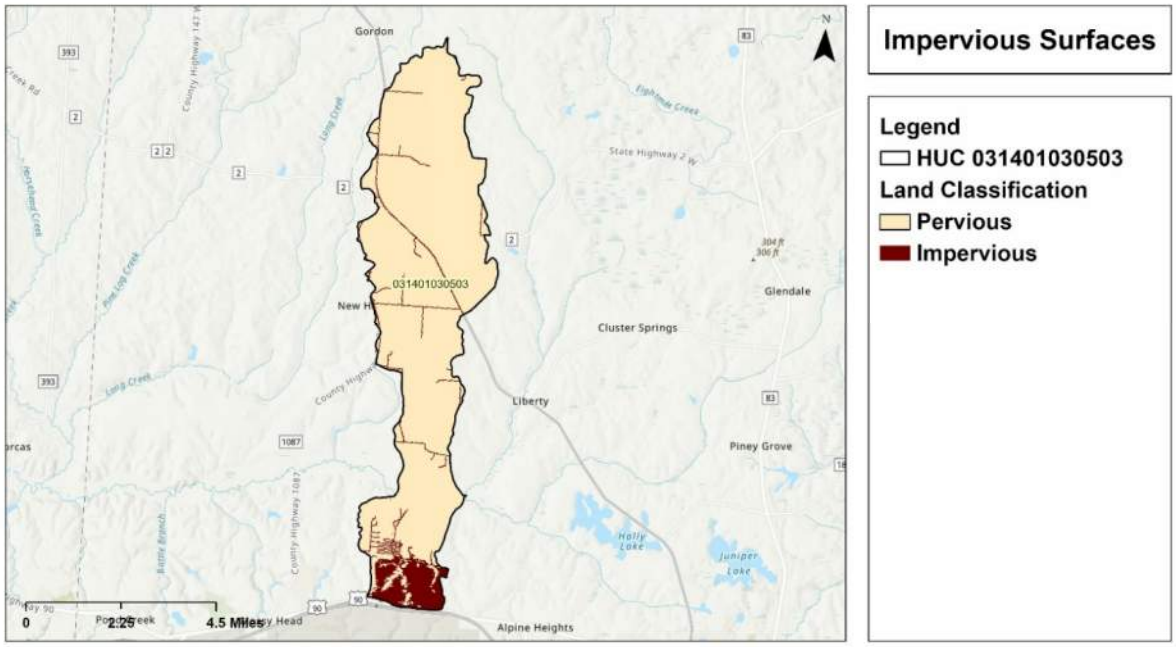

Figure 25. Impervious area map for the HUC 031401030503 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

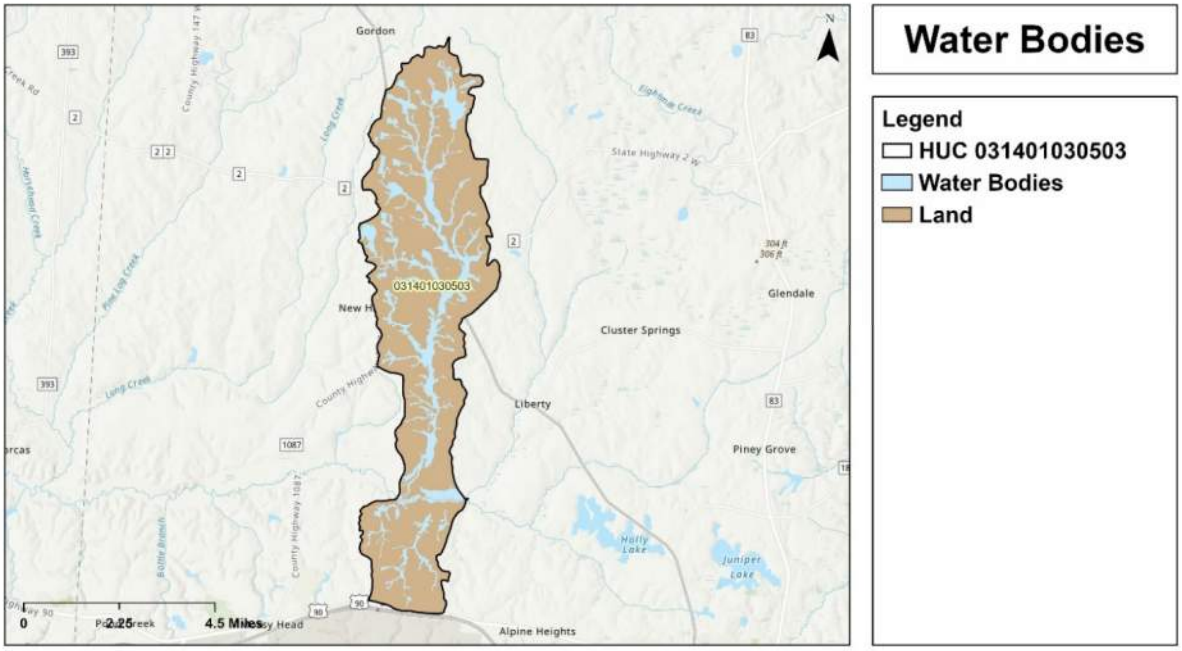

Figure 26. Water bodies map for the HUC 031401030503 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place.

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

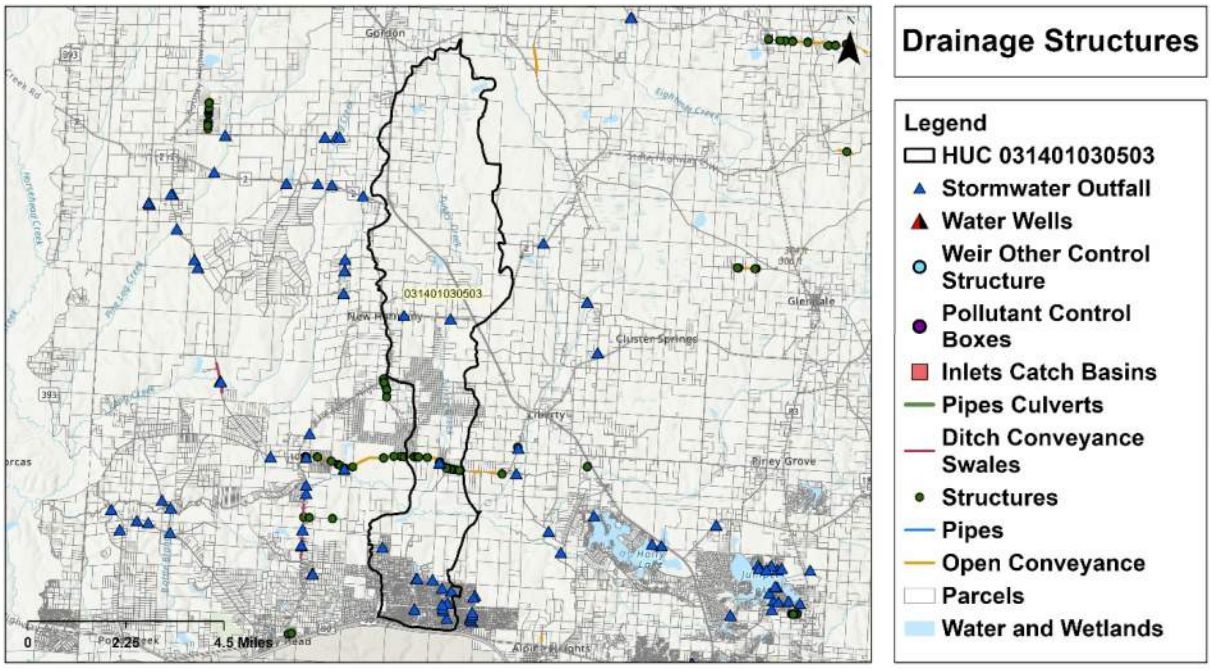

Figure 27. Stormwater Infrastructure for the HUC 031401030503. Processed by FAU.

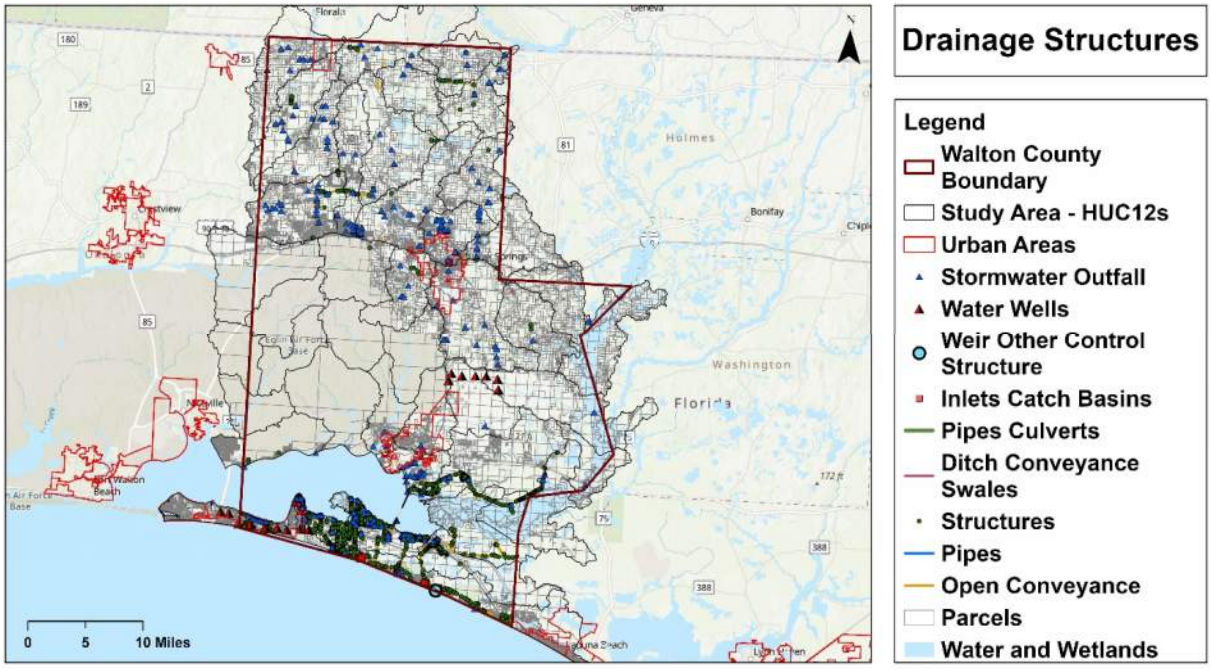

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030503 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

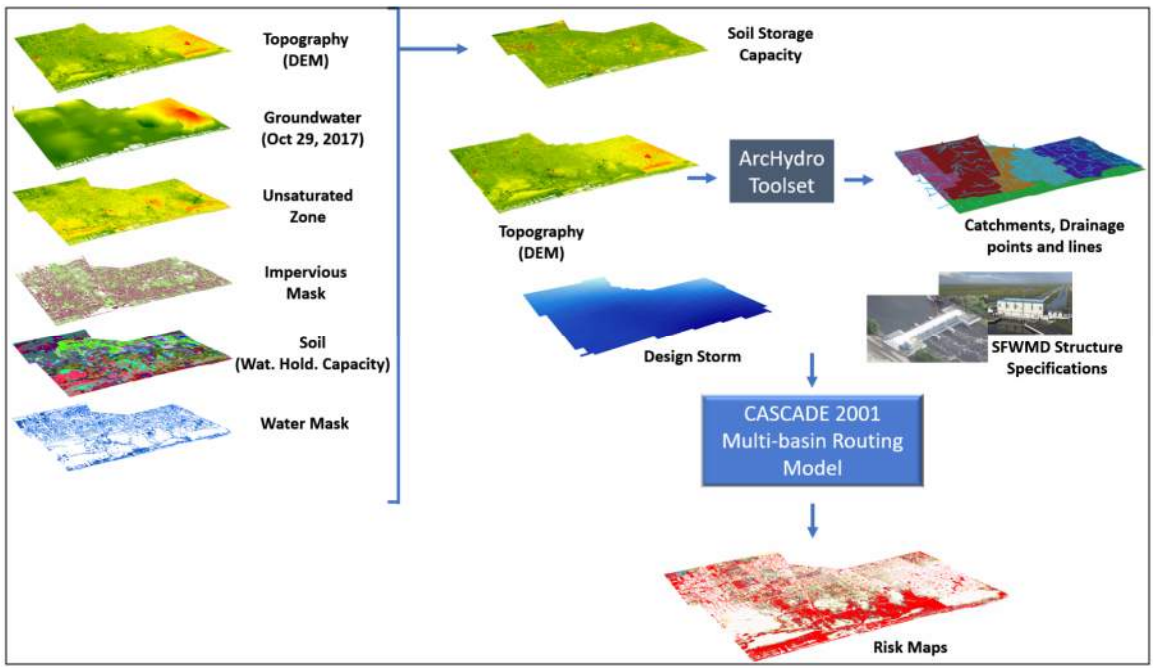

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

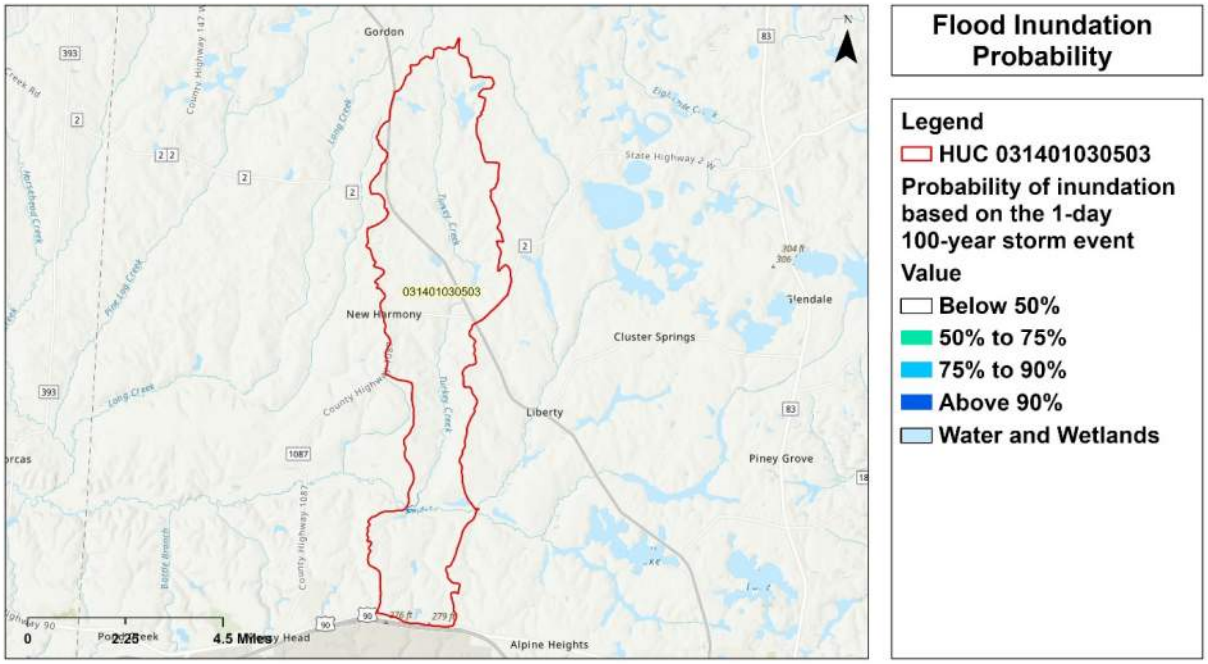

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030503, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees

and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a very small portion and almost imperceptible flooding is noted at the entrance to the creek into the HUC, due to its high altitudes. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not have impact on the area, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.1% of the HUC total area or 0.03 mi^2 has a probability of inundation above 50% for all four design storm, indicating that 0.03 mi^2 will be expected to be inundated in all four storm event scenarios. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030503 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	26.54	0.03	99.9%	0.1%
1-day 100-year	26.54	0.03	99.9%	0.1%
1-day 10-year	26.54	0.03	99.9%	0.1%
1-day 5-year	26.54	0.03	99.9%	0.1%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have

lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

88	Federal	6
89	Municipal	6
90	Leasehold Interests (Government-Owned Property Leased By A Non-Governmental Lessee)	6
91	Utility	1
92	Mining Lands, Petroleum Lands, or Gas Lands	6
93	Subsurface Rights	6
94	Right of Way	2
95	Submerged, lakes	6
96	Sewage Disposal	6
97	Outdoor Recreational Or Parkland, Or High-Water Recharge Subject To Classified Use Assessment	6
98	Centrally Assessed	6
99	Other Non-Agricultural Acreage	6
100	Parcel With no Values	6
101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is

converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401030503 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

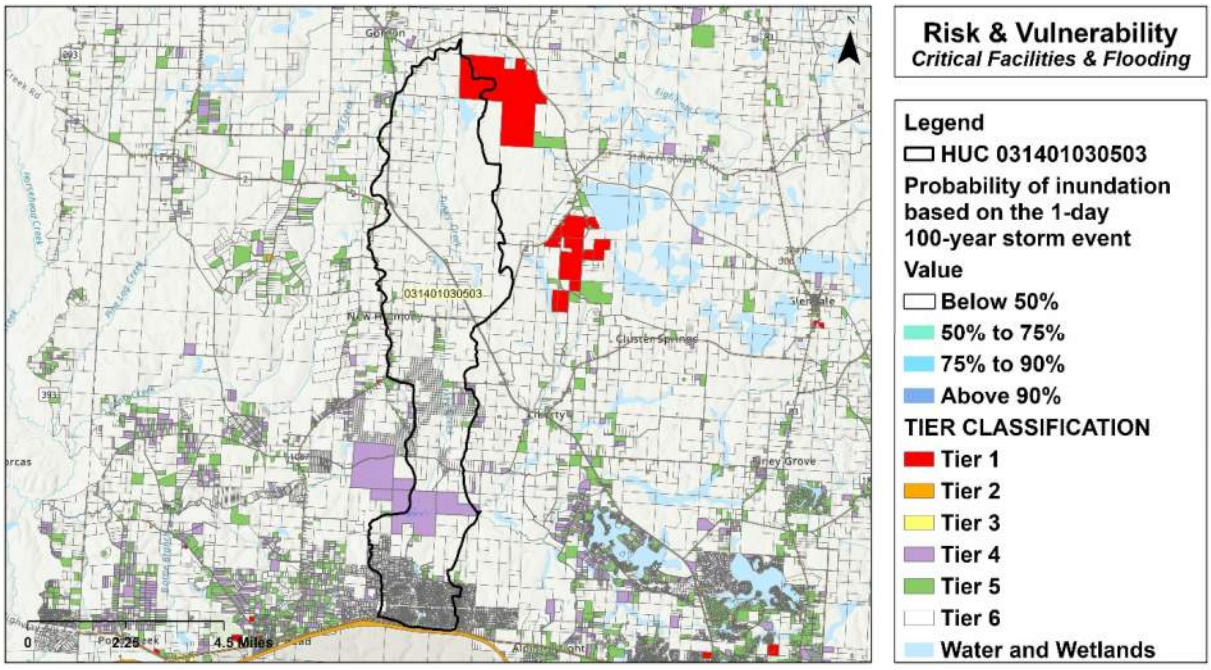

Figure 36. HUC 031401030503 sub-watershed Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

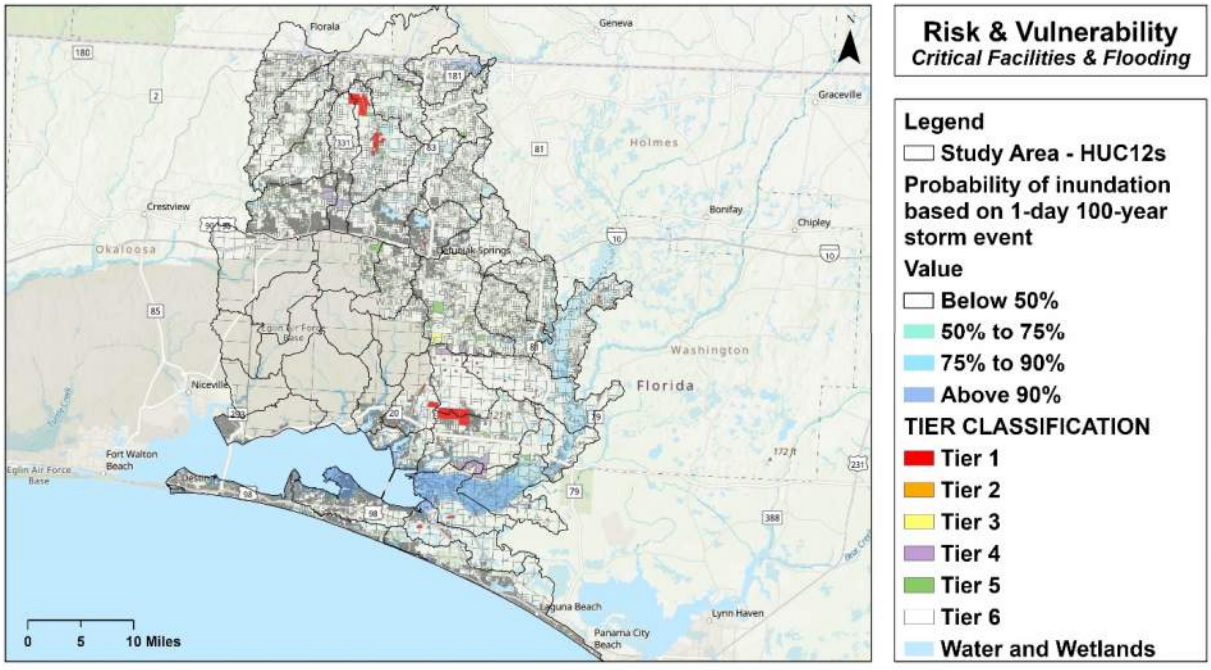

Figure 37. Walton County (mosaic) - Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation for Walton County. Processed by FAU.

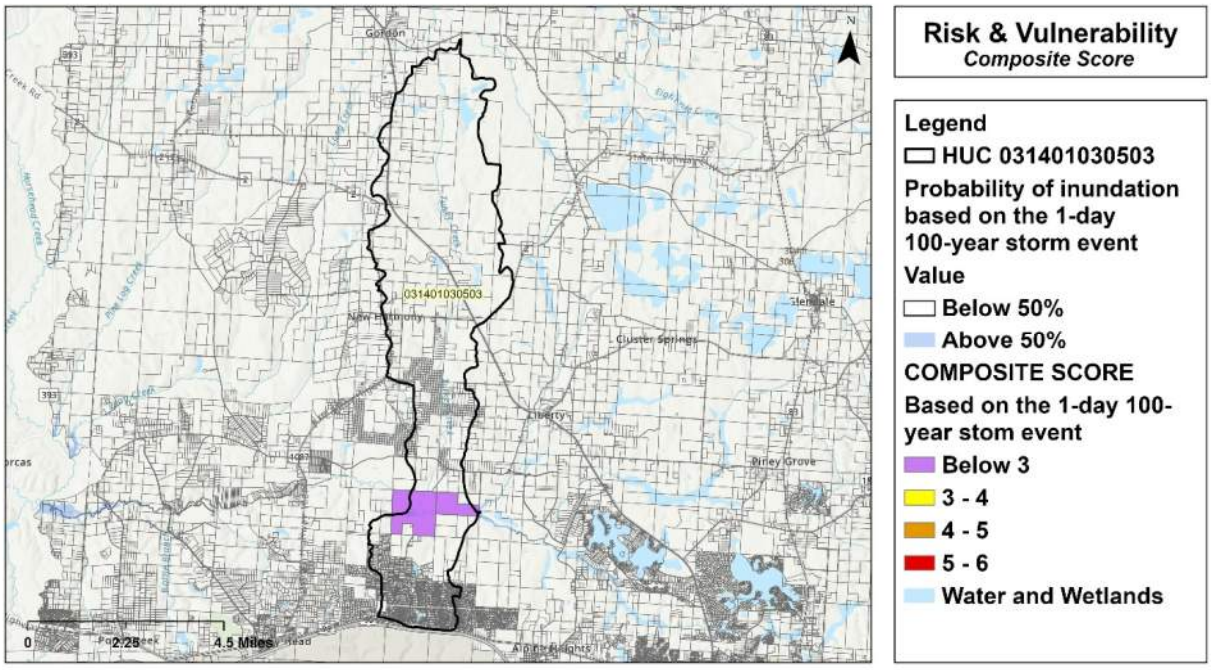

Figure 38. HUC 031401030503 sub-watershed Composite Score Risk map, with calculation based on 1-day 100-year storm event. Processed by FAU.

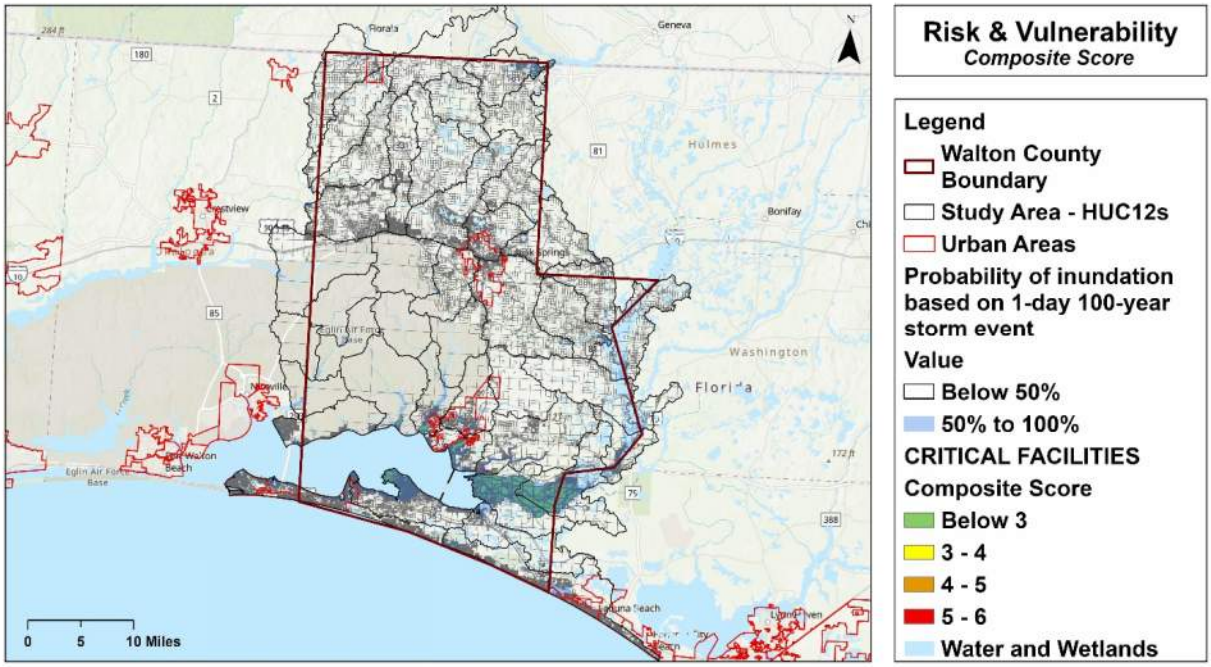

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030503. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030503. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030503	17000.11
All of the 1-day 100-year storm event inundation	**17.30**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	17.30
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	17.30

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. . **Error! Reference source**

not found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

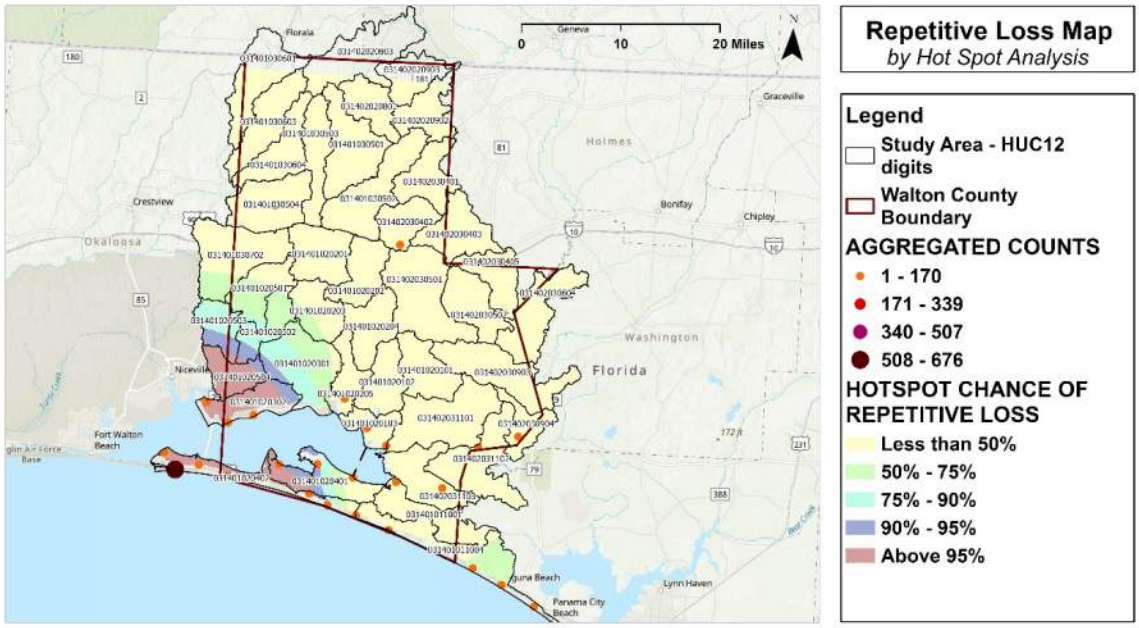

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are a few parcels falling within classification tier 1, and a good amount of parcels falling within tiers 4 and 5 of priority of land uses, only two of them are within the flooding zone, once flooding in the area is relatively minor and not alarming. Consequently, when considering the composite score, it is notable that there are only two parcels situated within the flooding zone that need some attention. They both have a score below 3, and are orphanages (DOR code 075), indicating a low priority of intervention.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030504) is highlighted among all the HUCs to help identifying its location. (Figure 3).

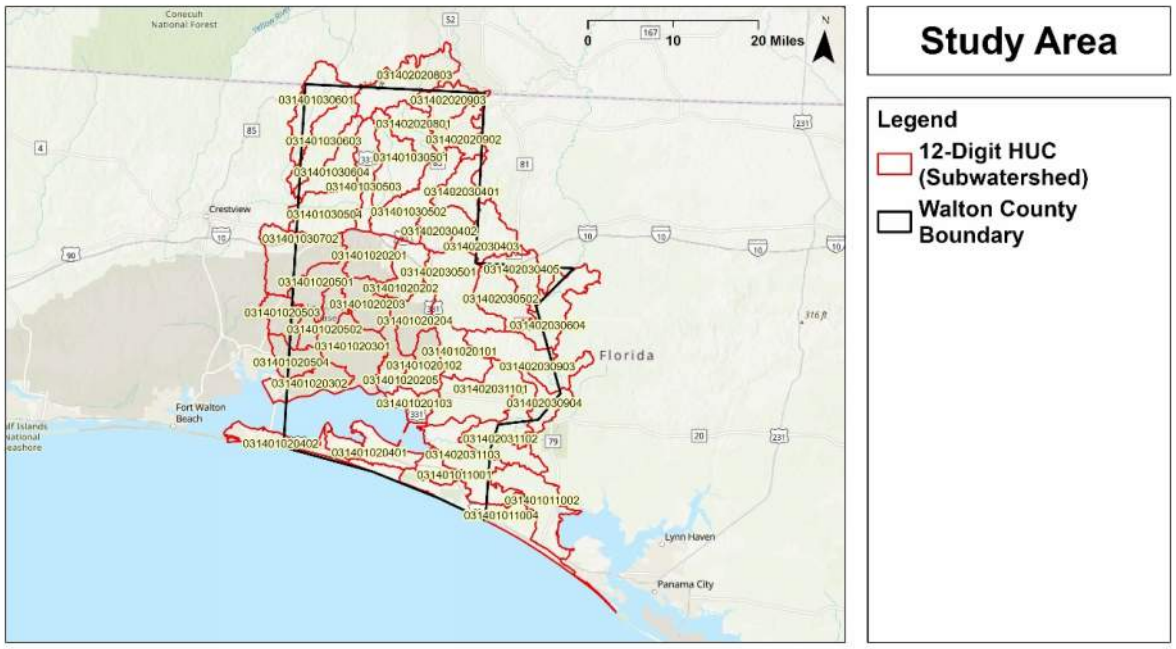

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

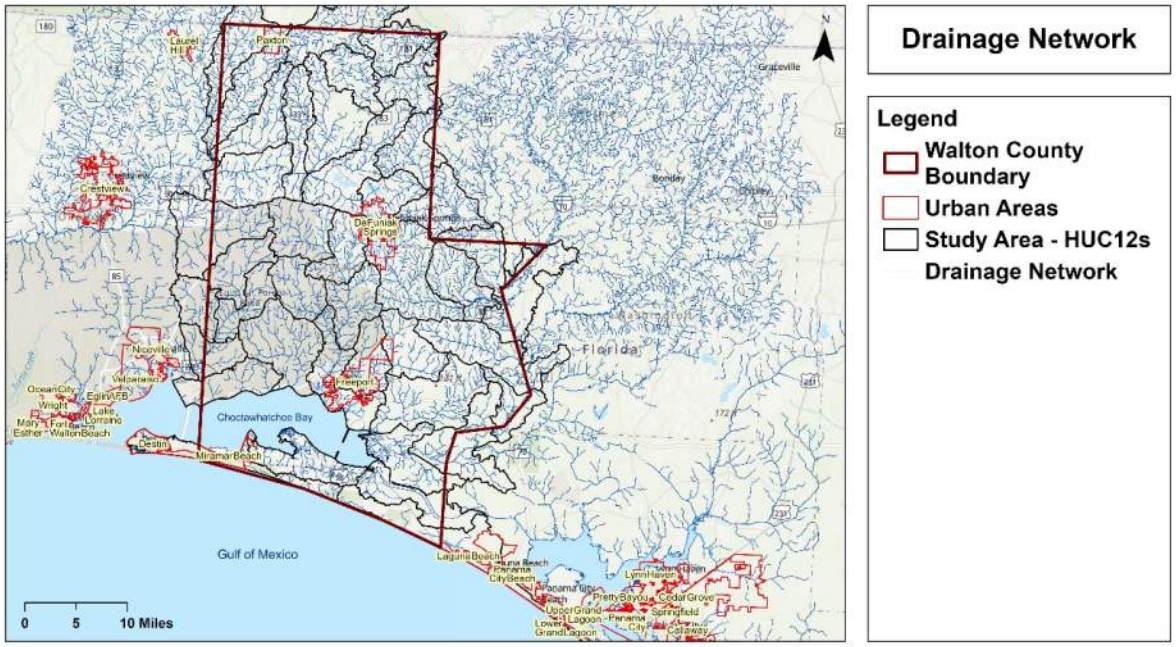

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

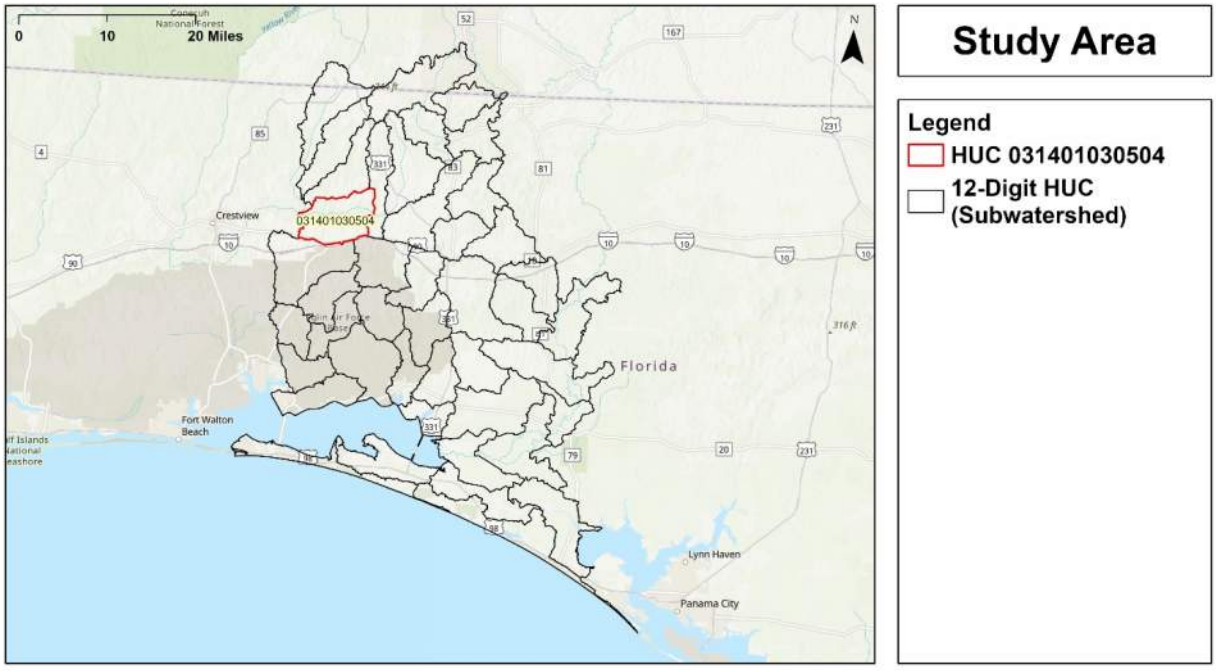

Figure 3. HUC 031401030504 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1. Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

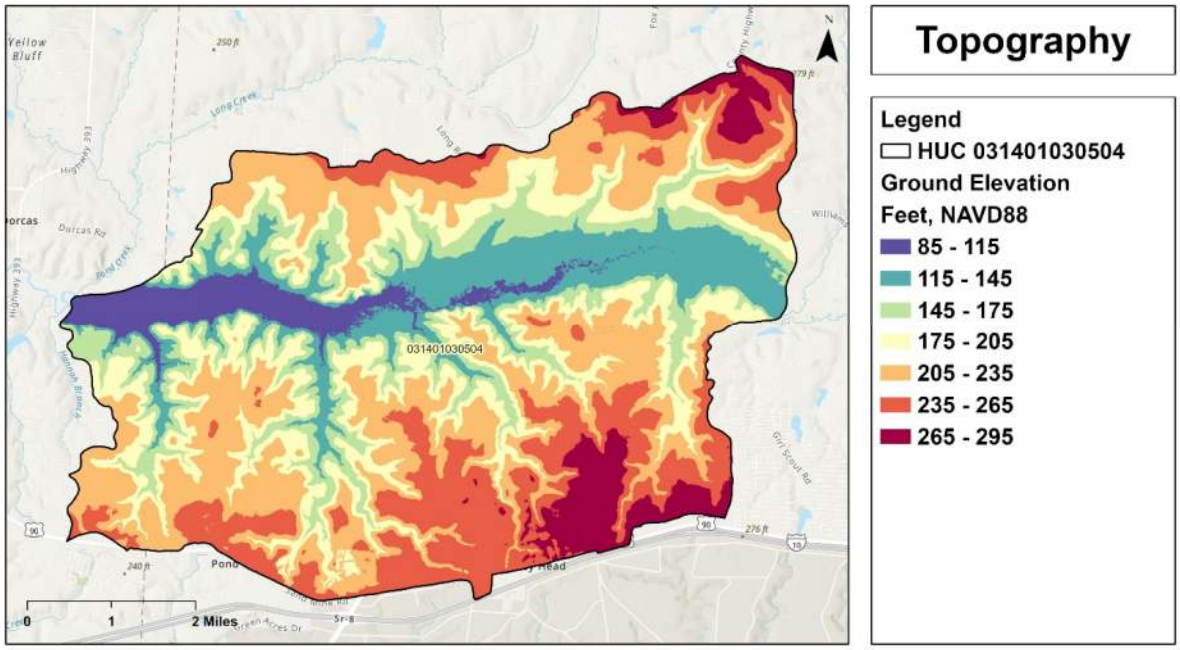

Figure 4. Topographic map of the HUC 031401030504 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030504 sub-watershed is shown in **Error! Reference source not found.**.

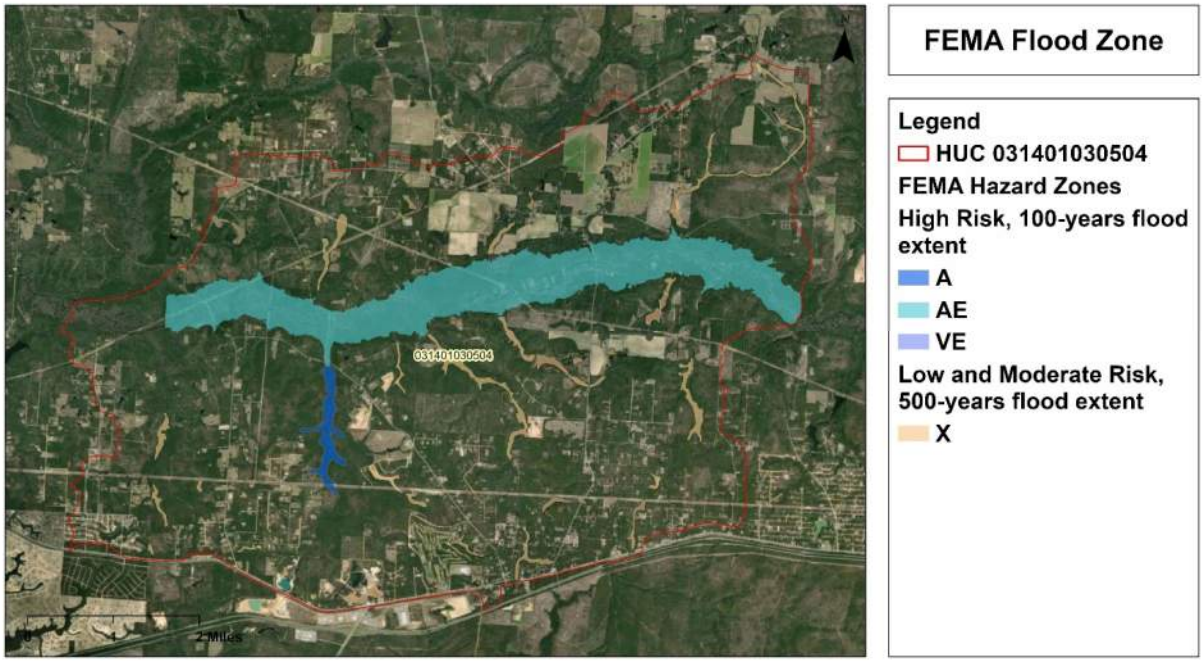

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030504 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes,

including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030504 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

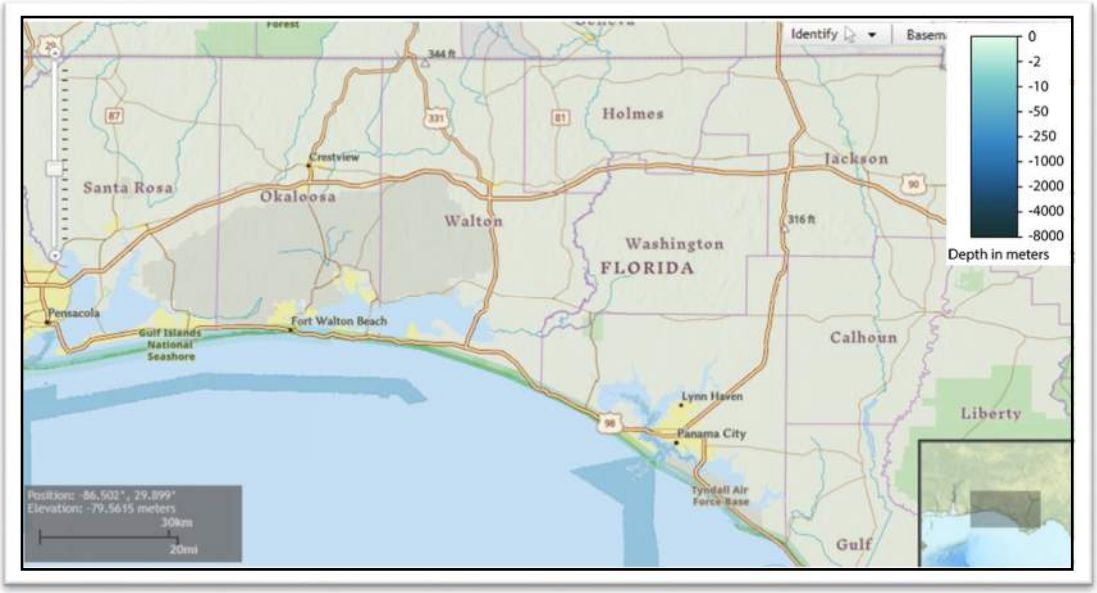

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle. Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

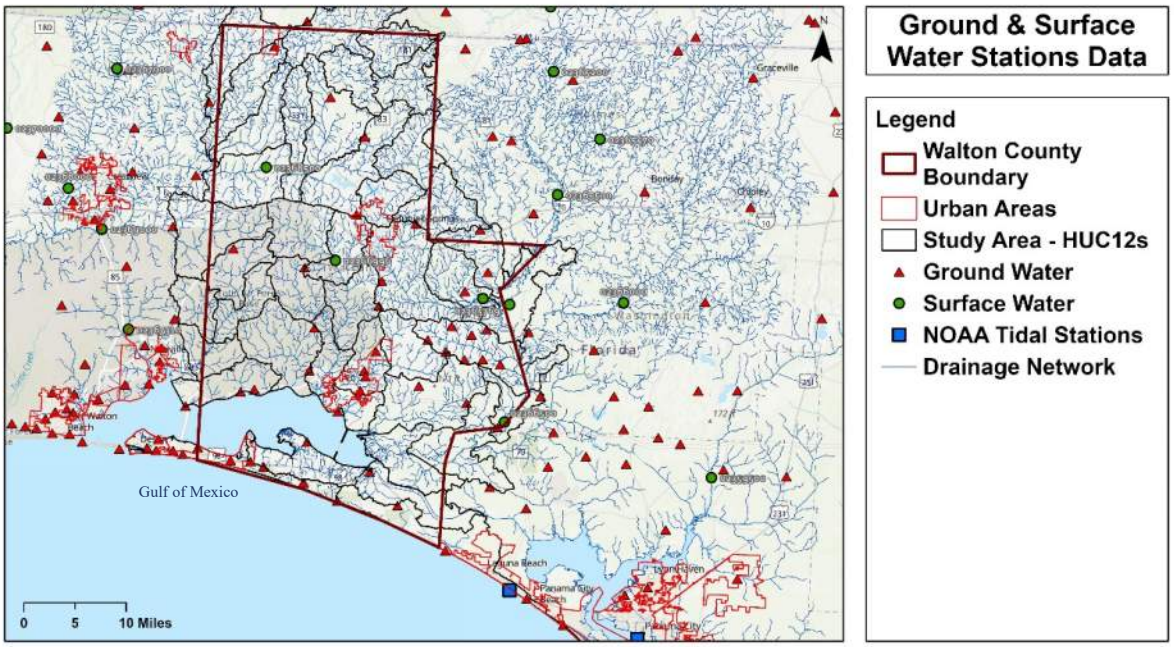

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The major water bodies in the HUC 031401030504 sub-watershed include:

- Shoal River
- Battle Creek

- Brown Branch
- Bottle Branch
- Boggy Branch
- Mill Creek
- Machine Branch
- Tan Branch
- Wolf Branch
- Tan Branch
- Laird Mill Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030503, which is USGS 02368500 Shoal River.

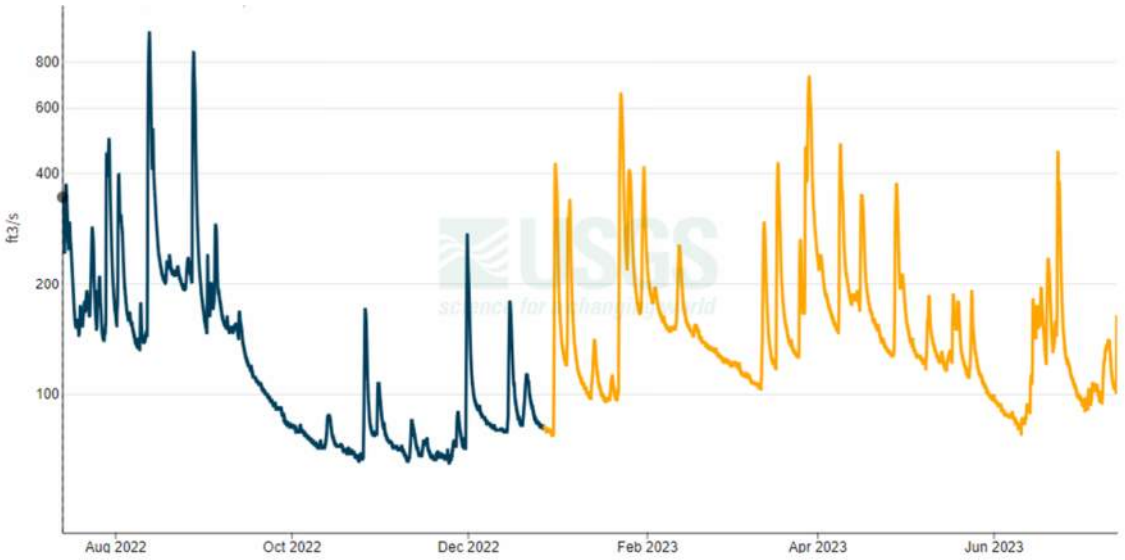

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish

a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030504 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401030504 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

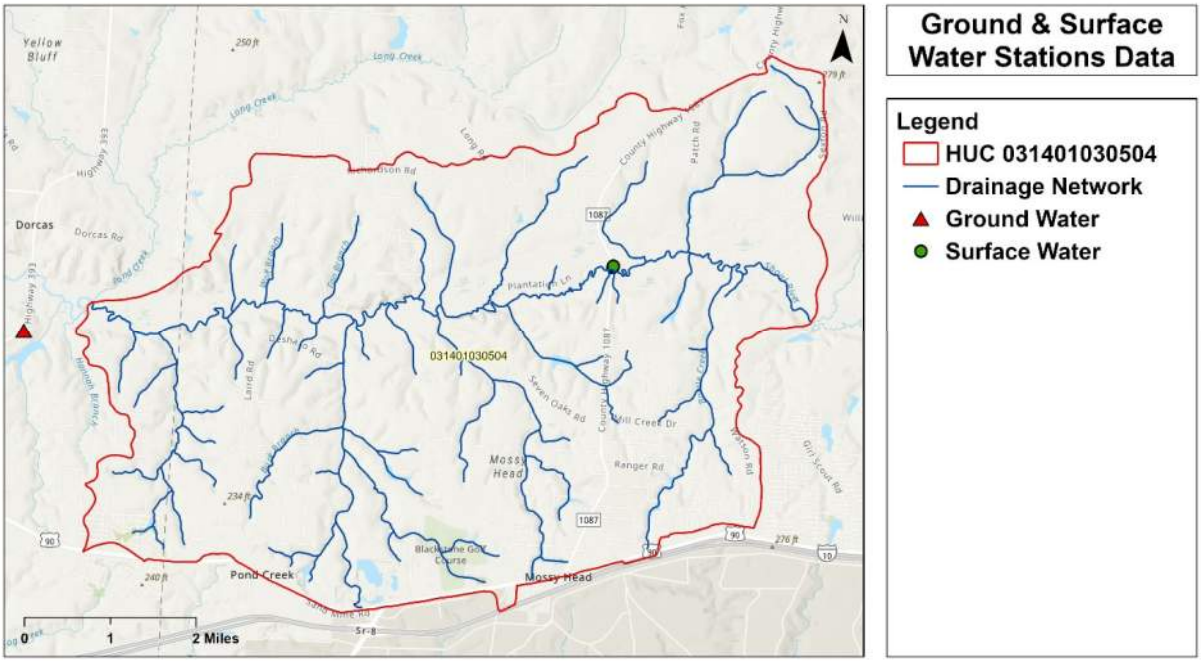

Figure 9. Ground and Surface Water Stations in the HUC 031401030504 sub-watershed, processed by FAU.

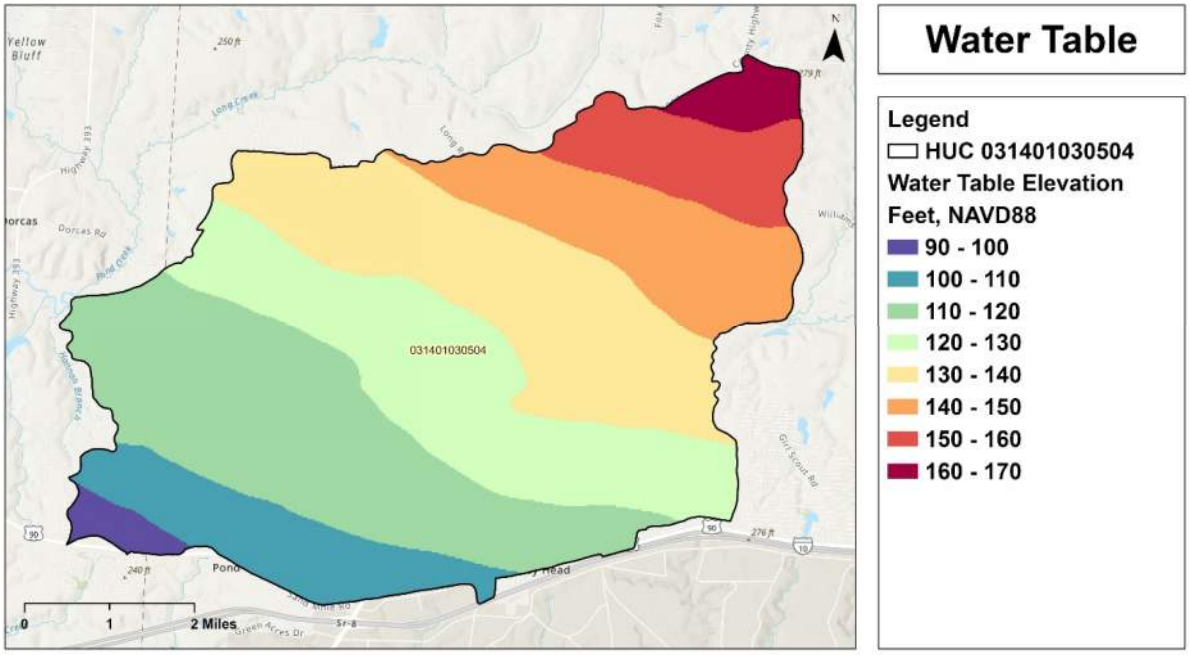

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030504 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

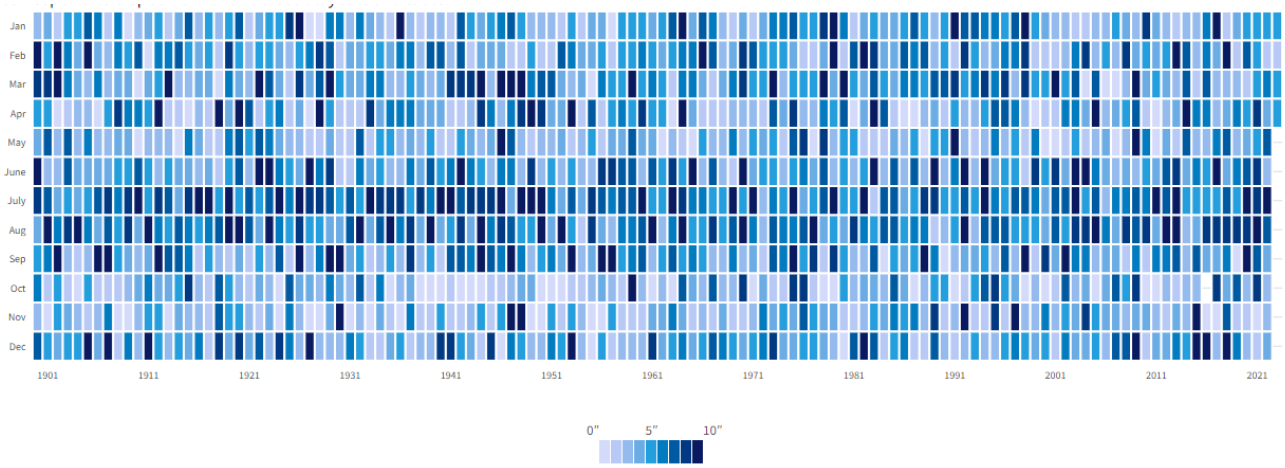

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/).

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

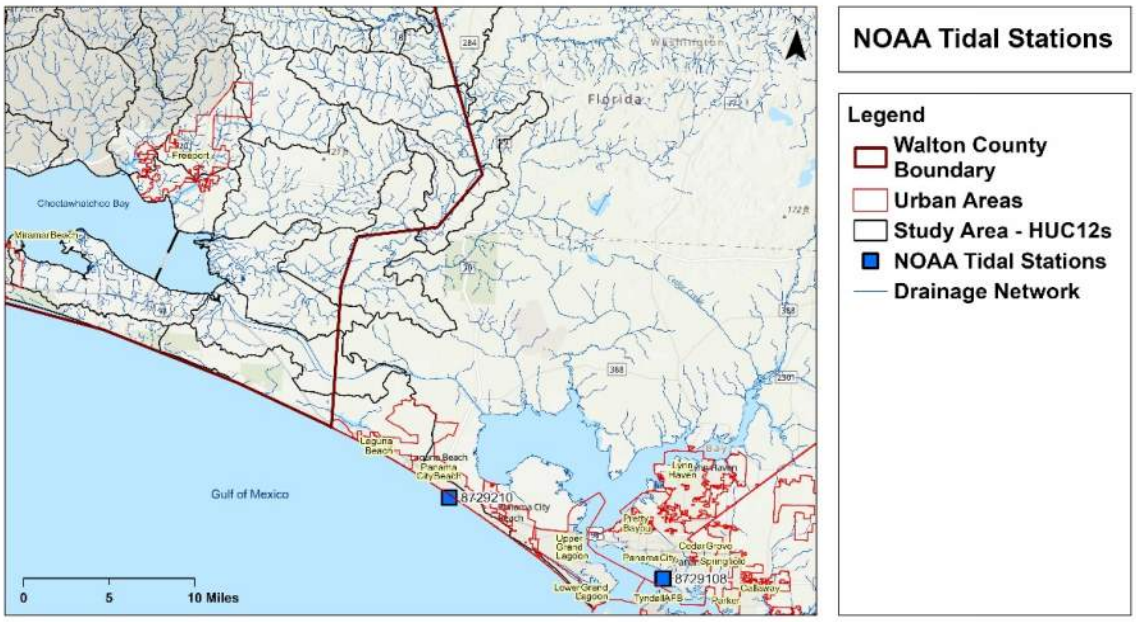

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

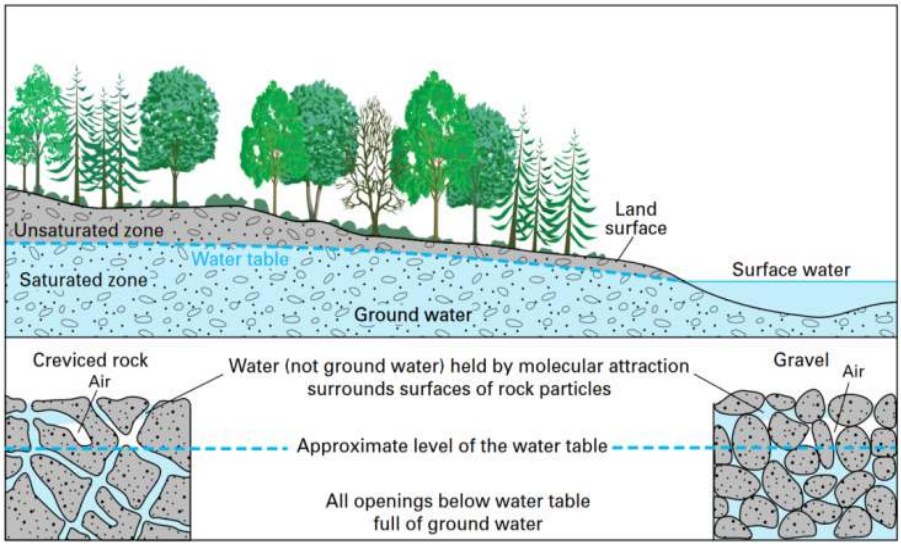

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

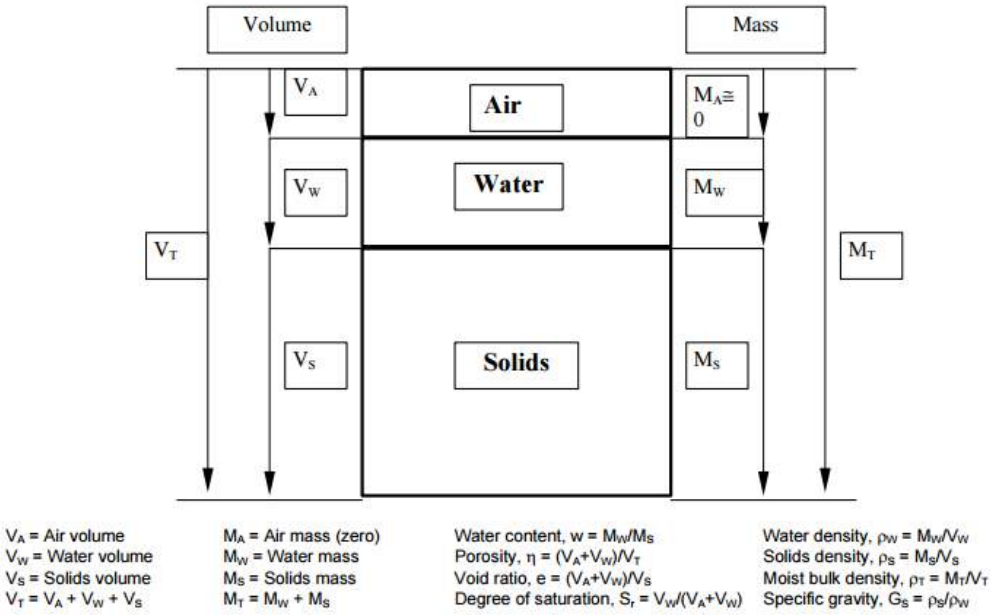

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

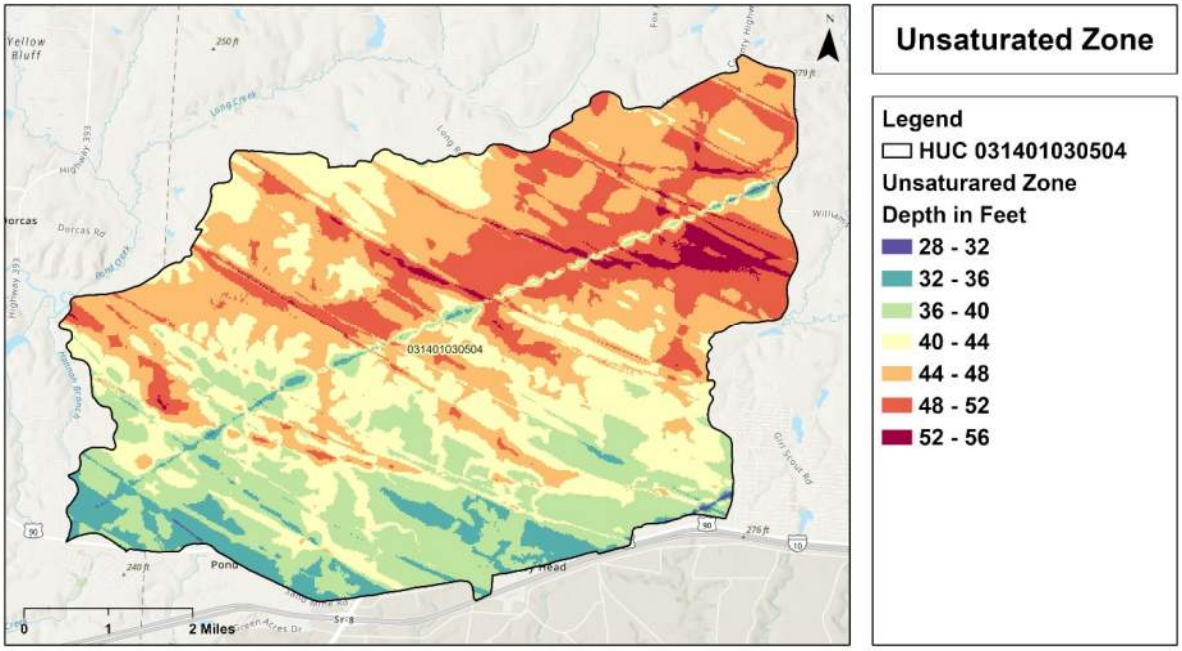

Figure 15. Unsaturated zone map for HUC 031401030504, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated.

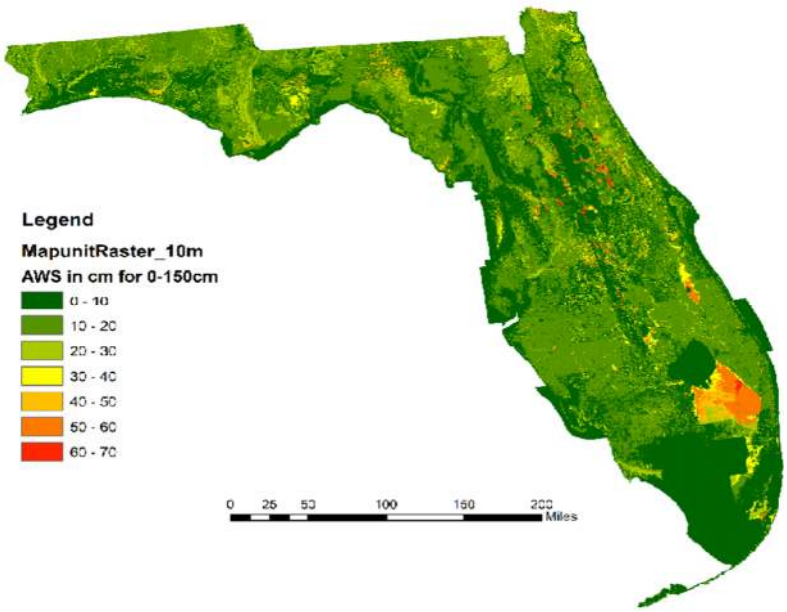

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, processed by FAU.

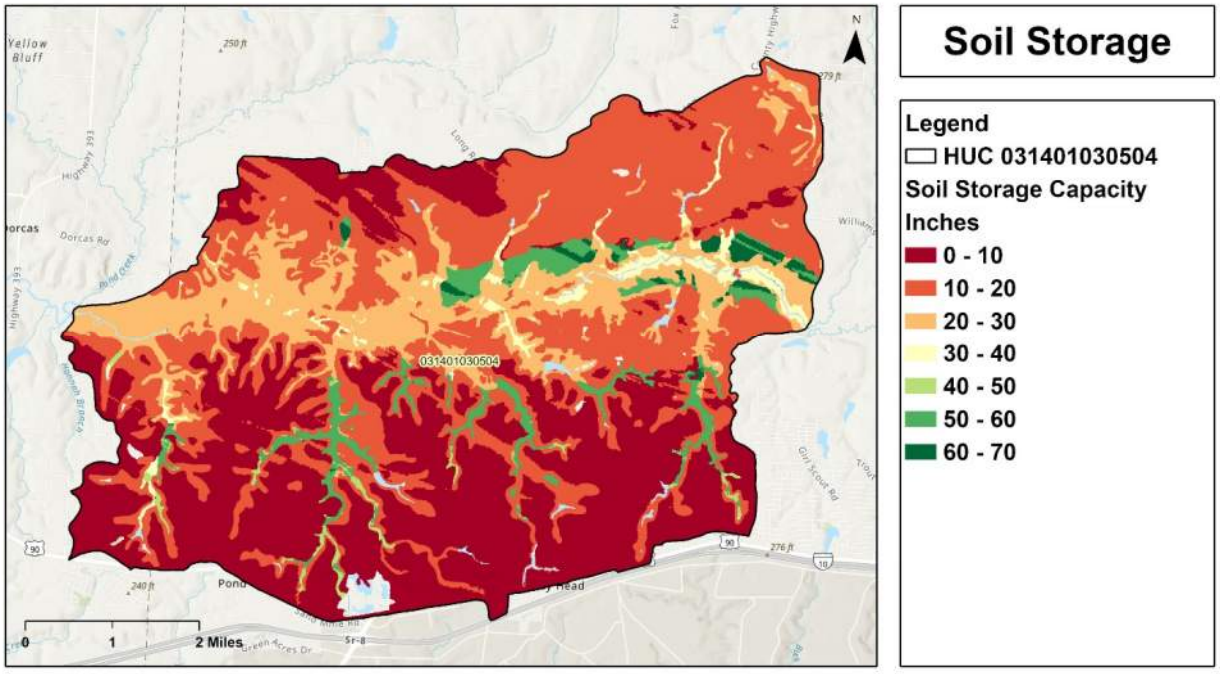

Figure 17. Water storage capacity of soil for the HUC 031401030504, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

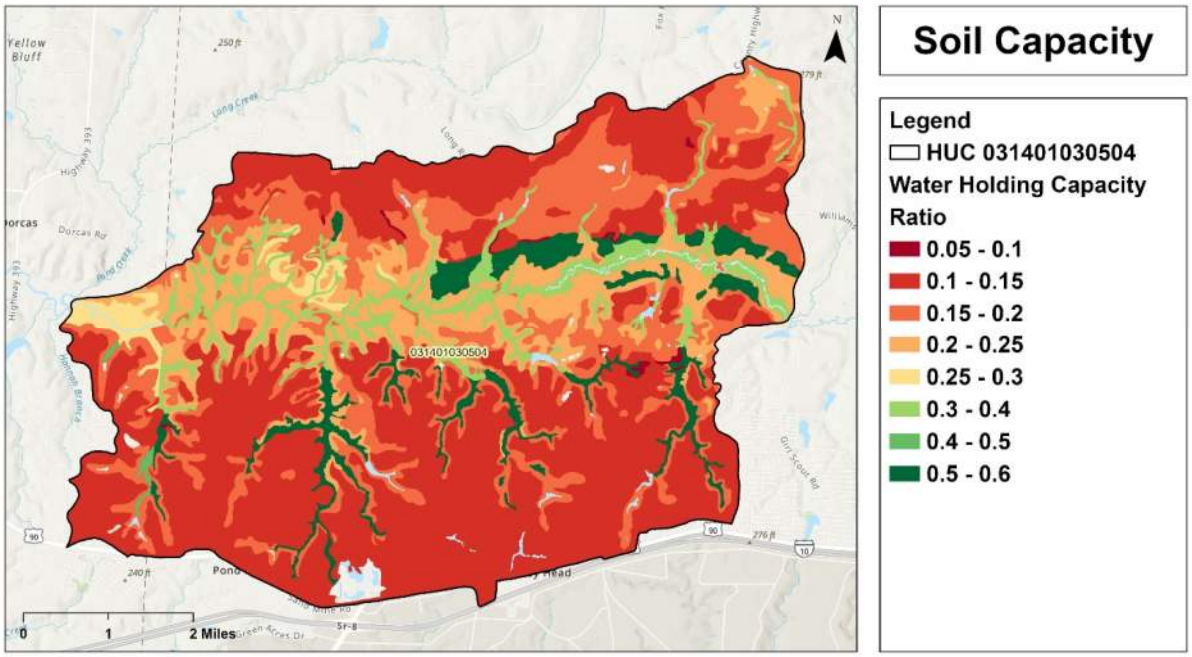

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030504, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

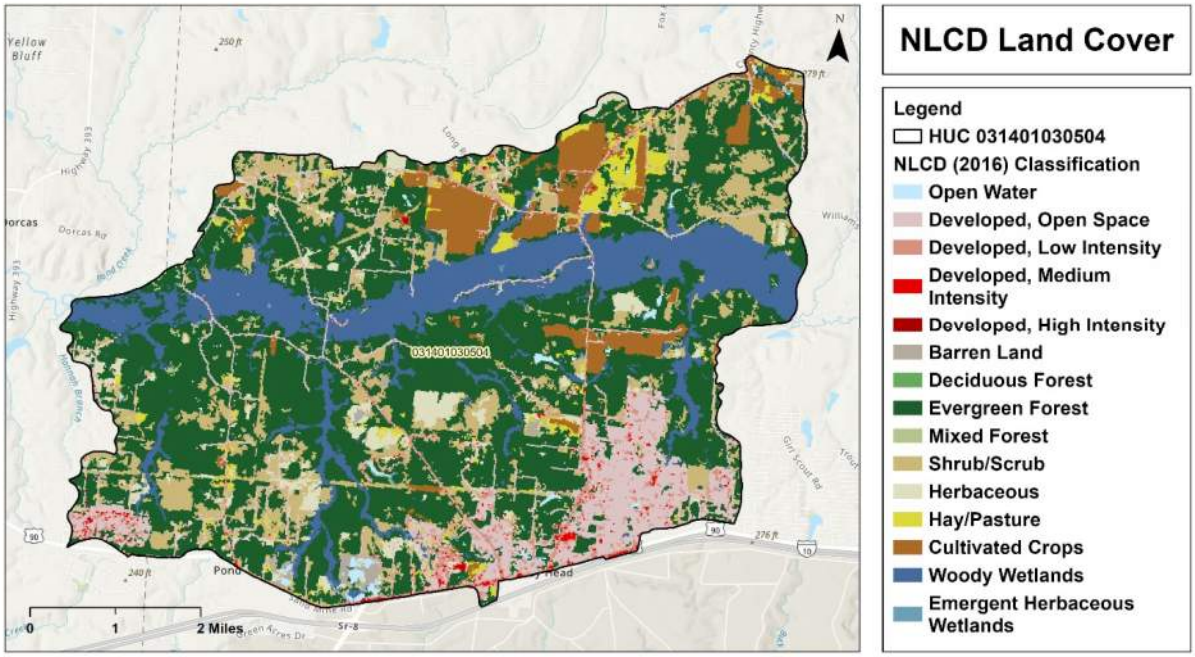

Figure 19. Land use in the HUC 031401030504 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps were used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

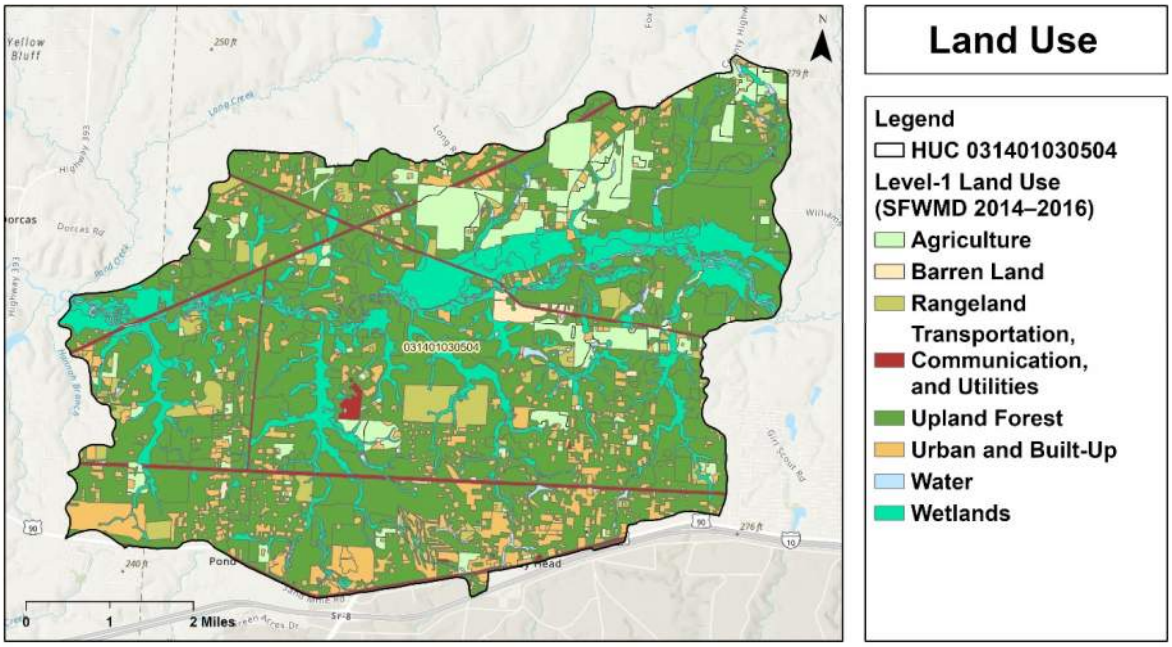

Figure 20. Land use in the HUC 031401030504 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031401030502 sub-watershed, mostly of the area is upland forest, with 51.85%. The second place is wetland, with 12.95% followed by Transportation, Communication, and Utilities, with 12.14%. Urban and built-up also represent a good amount, with 10.33% of the total, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030502 subwatershed (from the 2023 Florida Geographic Data Library (FGDL) database).

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	2098.72	6.94%
Barren Land	165.04	0.55%
Rangeland	1102.05	3.64%
Transportation, Communication, and Utilities	3670.46	12.14%
Upland Forest	15681.31	51.85%
Urban and Built-Up	3124.41	10.33%
Water	484.09	1.60%
Wetlands	3915.29	12.95%
Grand Total:	**30241.37**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

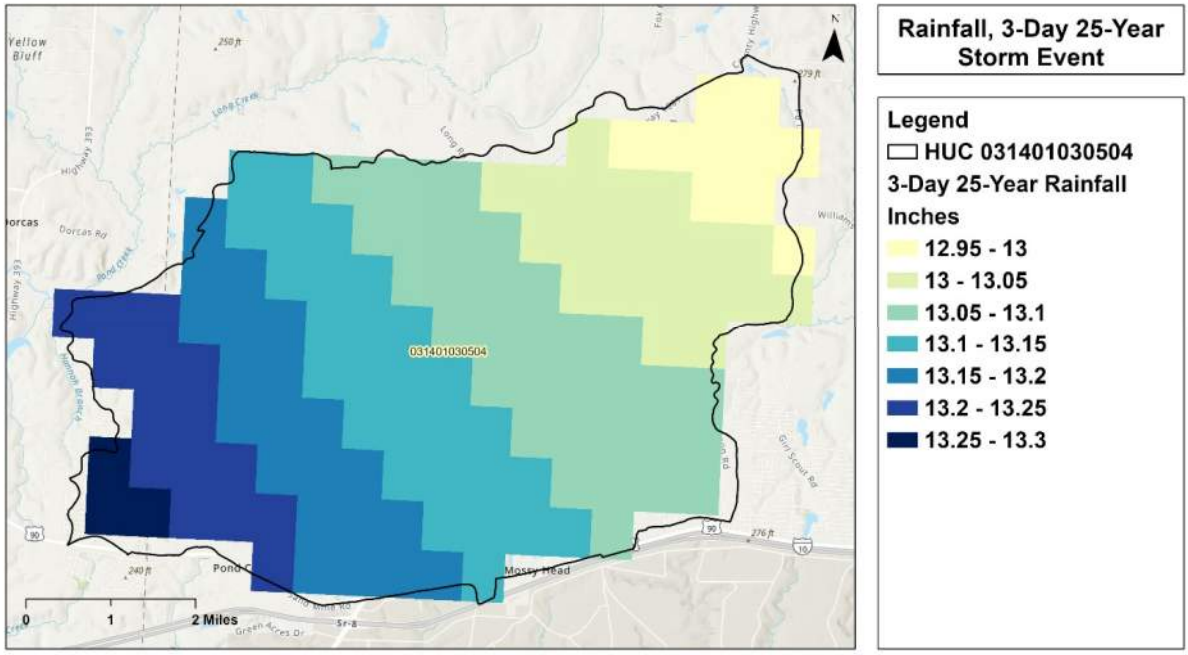

Figure 21. Rainfall distribution map across HUC 031401030504 sub-watershed, for 3-day 25-year storm event, processed by FAU.

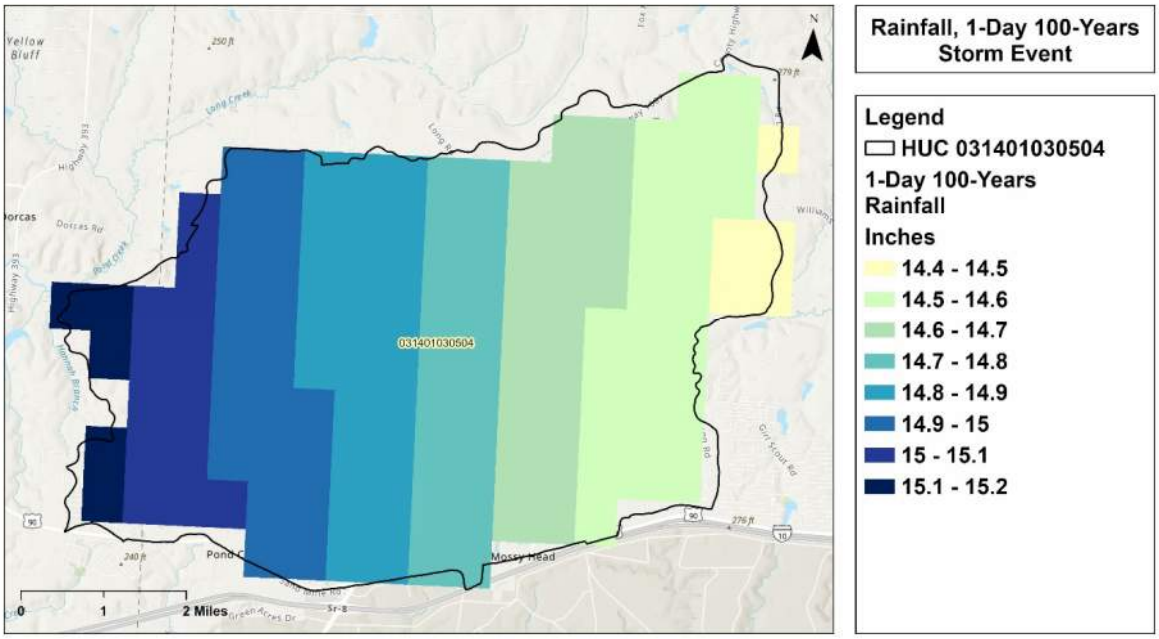

Figure 22. Rainfall distribution map across HUC 031401030504 sub-watershed, for 1-day 100-year storm event, processed by FAU.

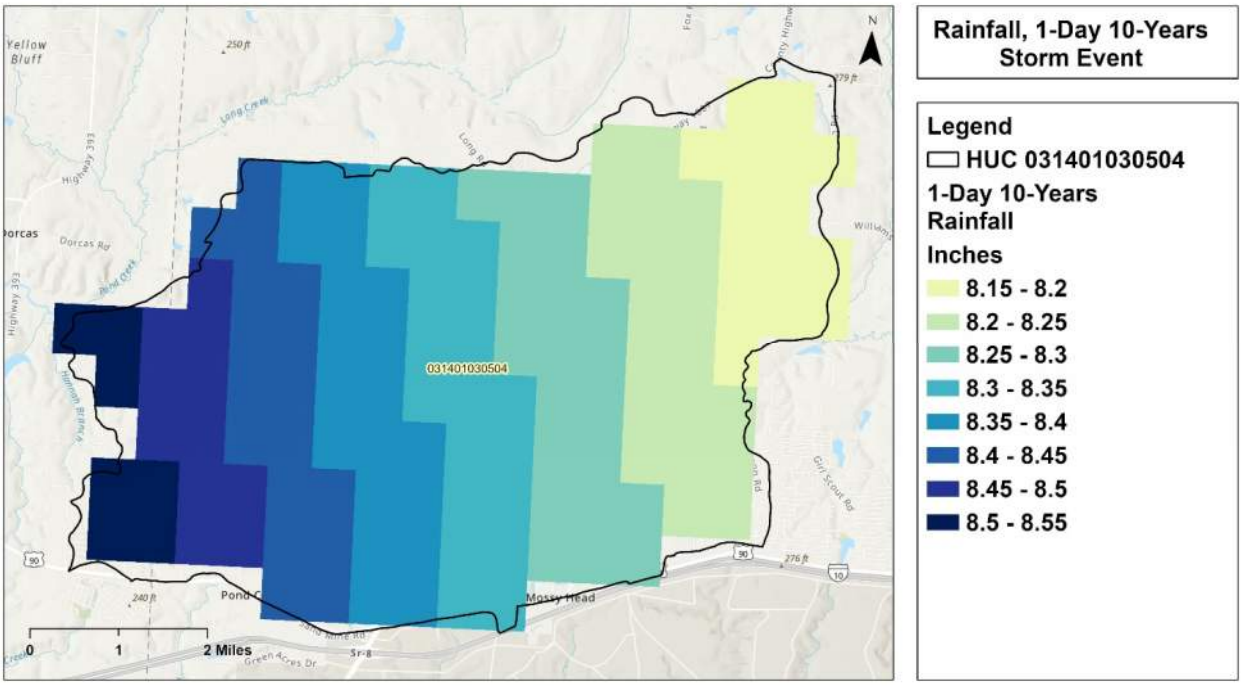

Figure 23. Rainfall distribution map across HUC 031401030504 sub-watershed, for 1-day 10-year storm event, processed by FAU.

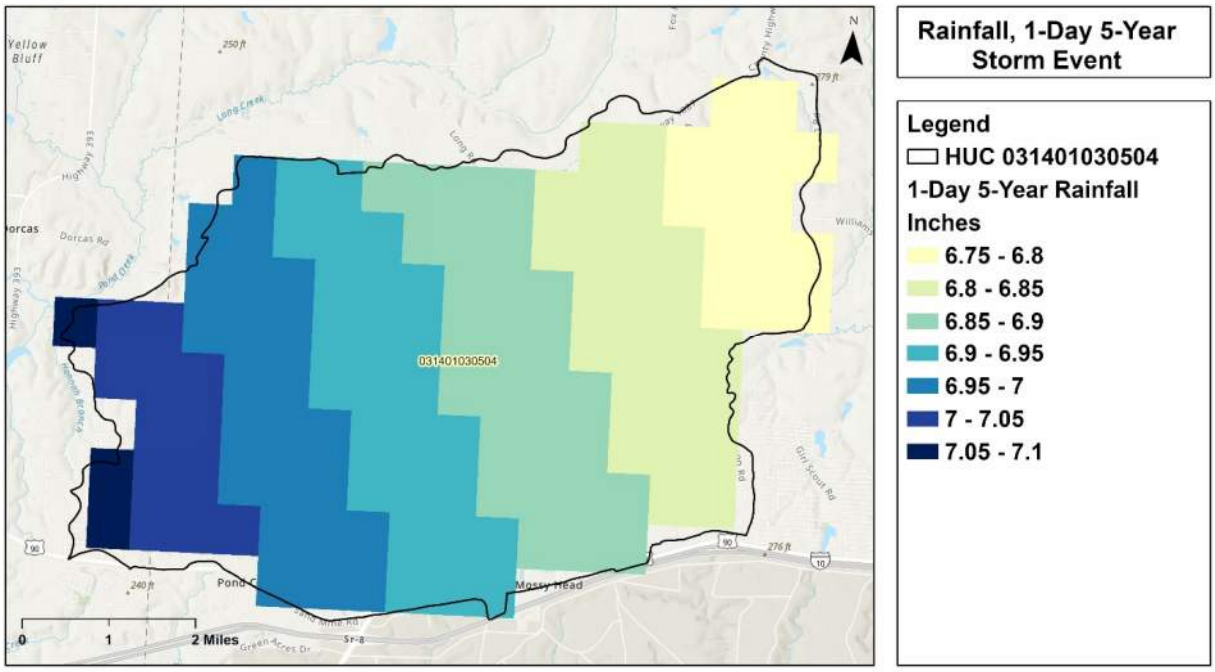

Figure 24. Rainfall distribution map across HUC 031401030504 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically

aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

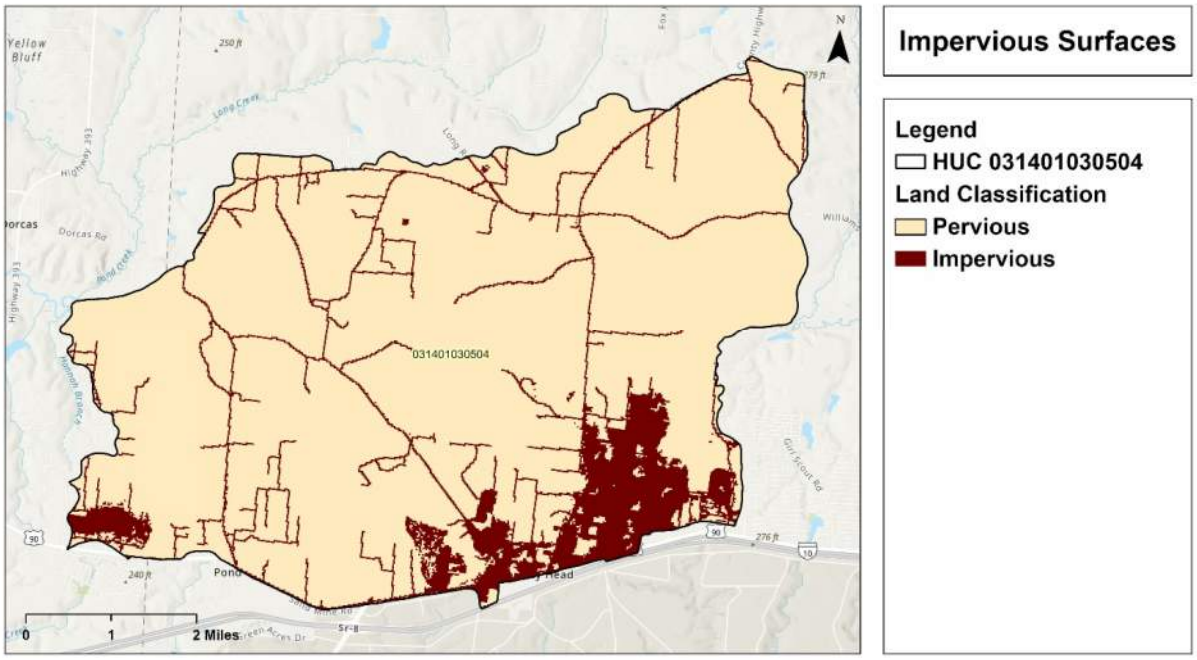

Figure 25. Impervious area map for the HUC 031401030504 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

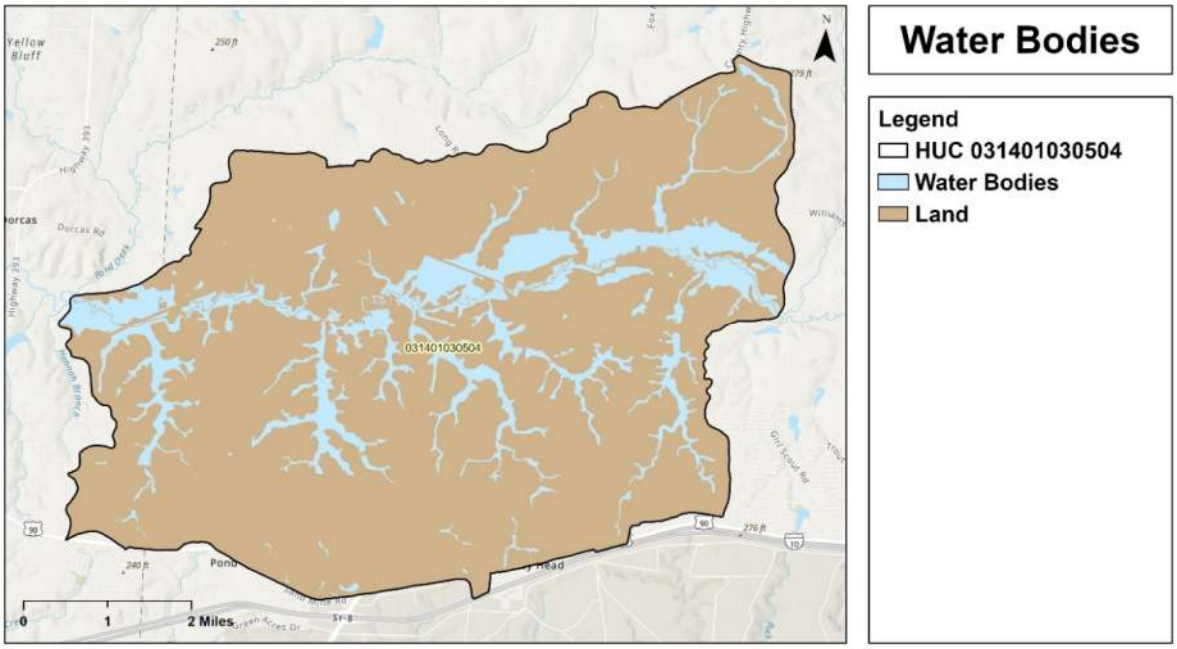

Figure 26. Water bodies map for the HUC 031401030504 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs,

property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.** respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

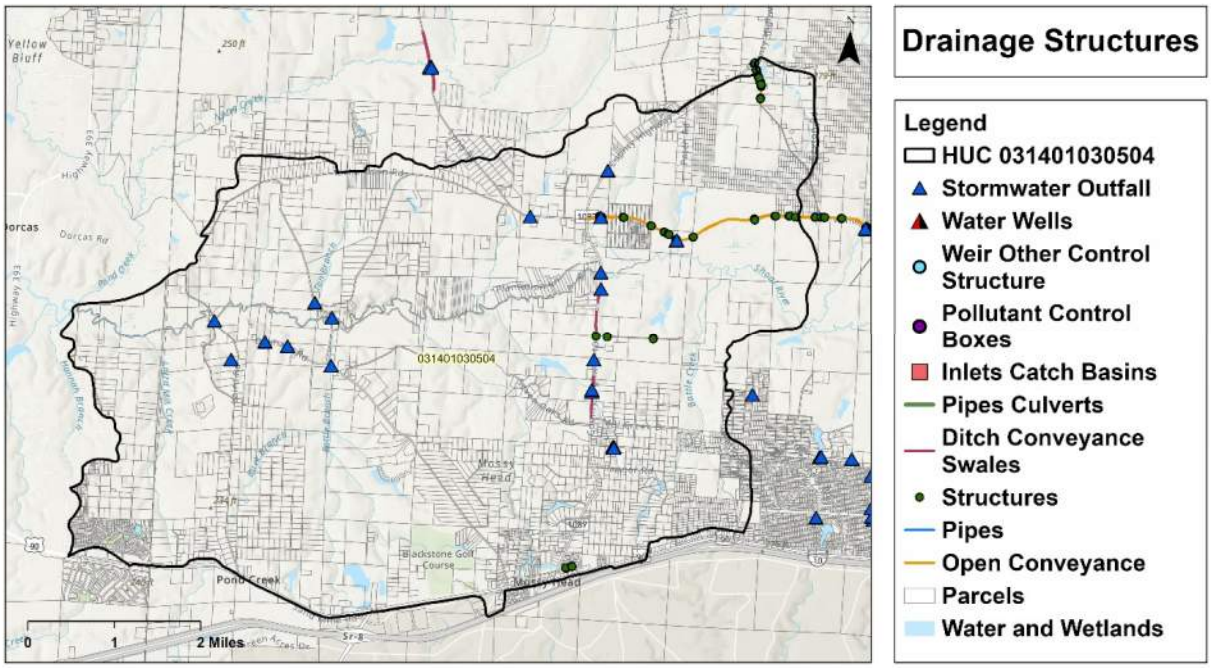

Figure 27. Stormwater Infrastructure for the HUC 031401030504. Processed by FAU.

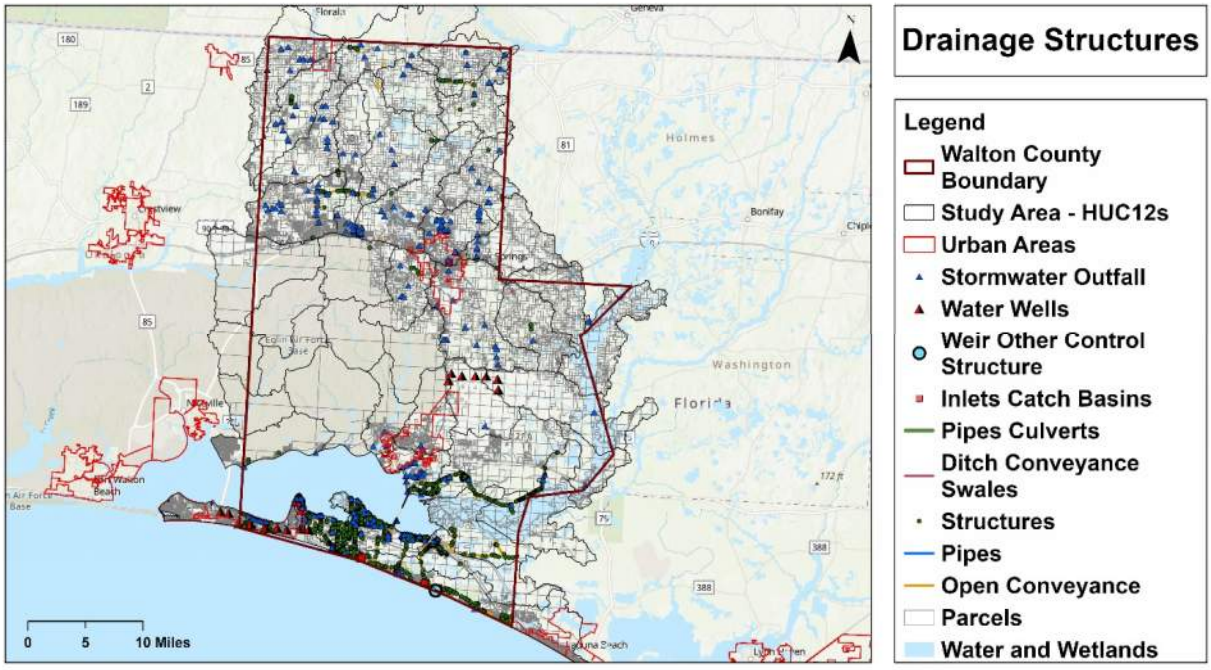

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030504 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

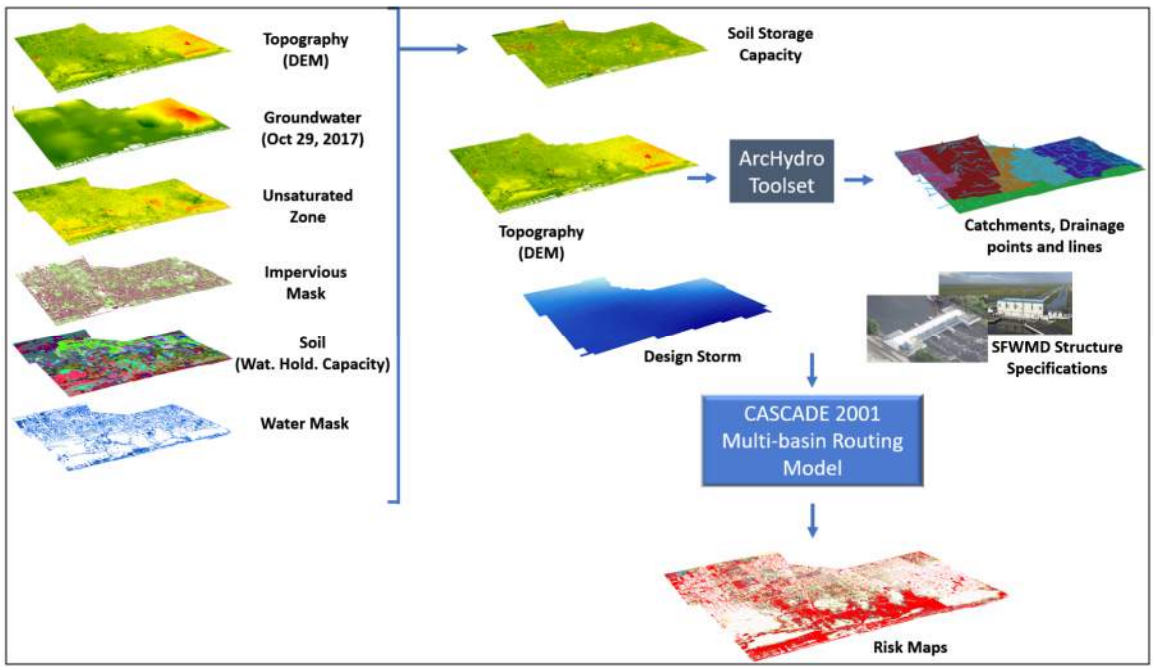

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

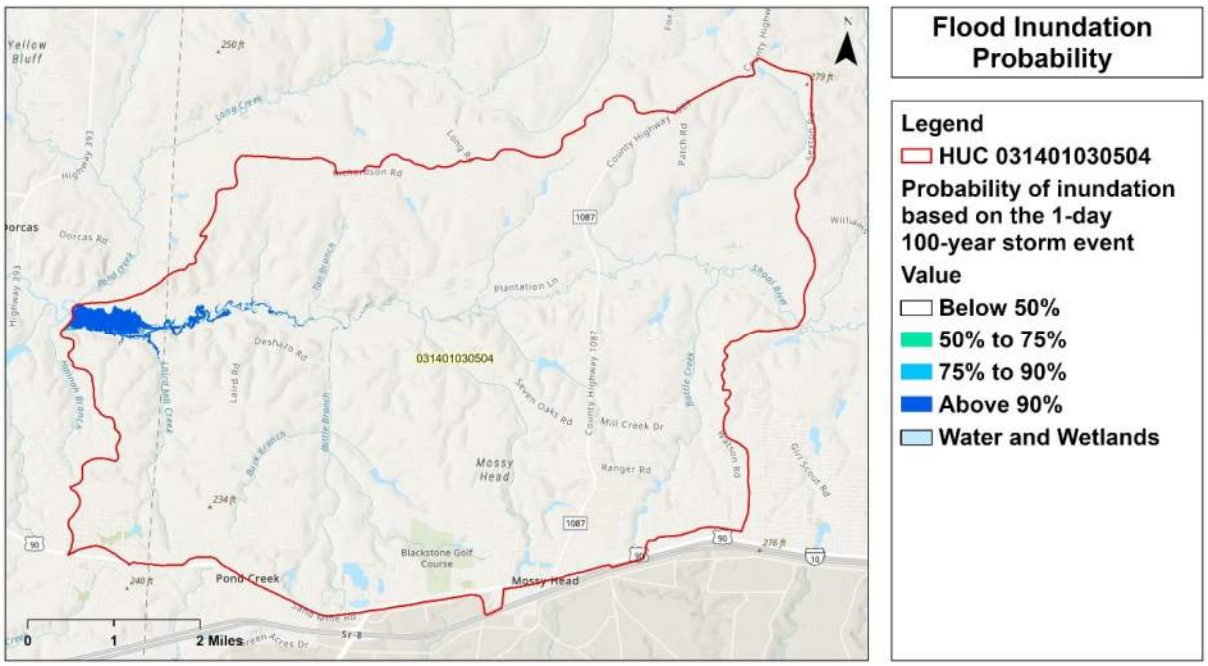

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030504, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data

to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the entrance of Shoal River into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.8% of the HUC total area or 0.29 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.9% of the HUC's total area, or 0.36 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.6% of the HUC's total area, or 0.23 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.4% of the HUC's total area, or 0.17 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030504 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	37.69	0.29	99.2%	0.8%
1-day 100-year	37.62	0.36	99.1%	0.9%
1-day 10-year	37.75	0.23	99.4%	0.6%
1-day 5-year	37.81	0.17	99.5%	0.4%

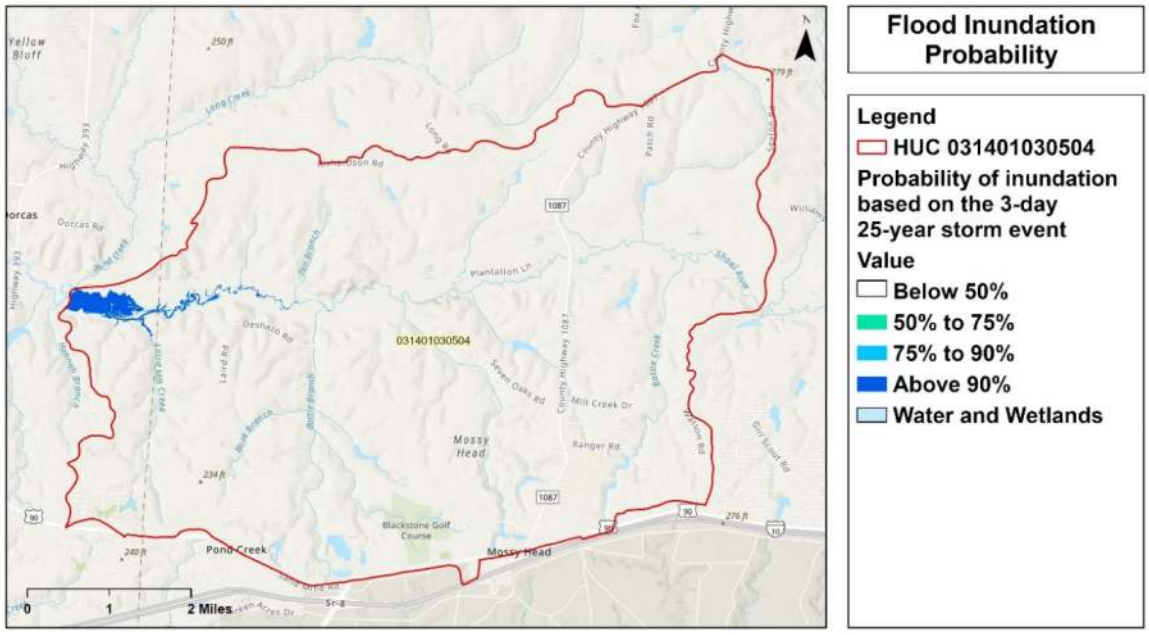

Figure 31. 3-day 25-year storm event for HUC 031401030504 sub-watershed. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

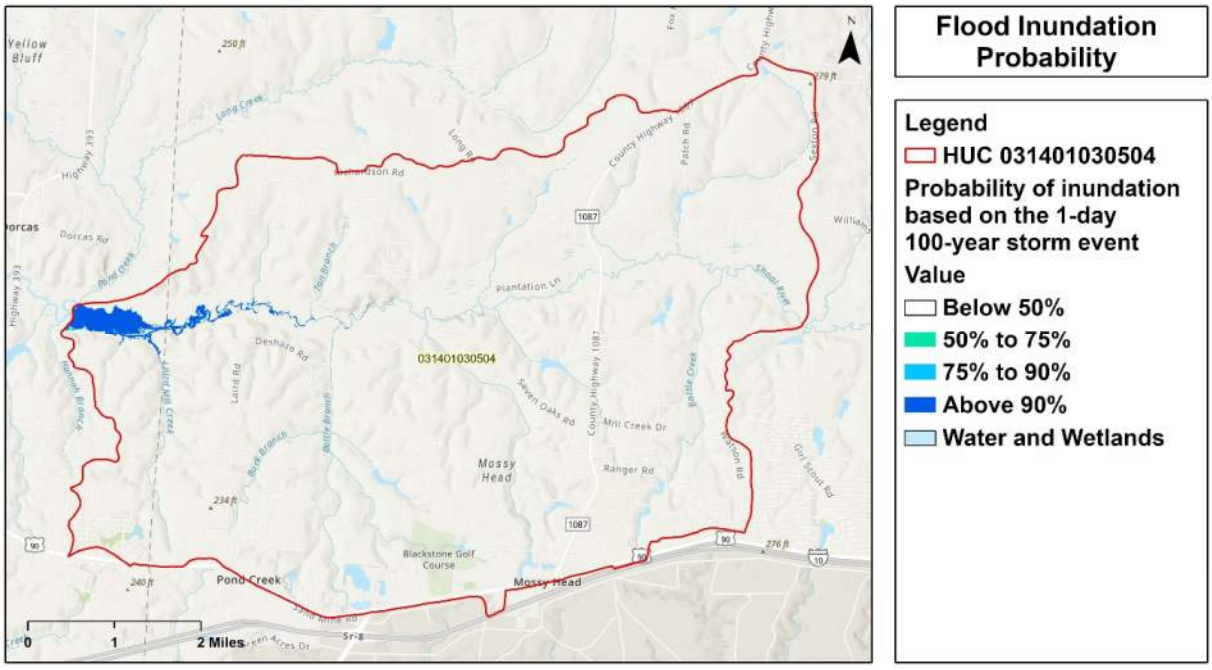

Figure 32. 1-day 100-year storm event for HUC 031401030504 sub-watershed. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

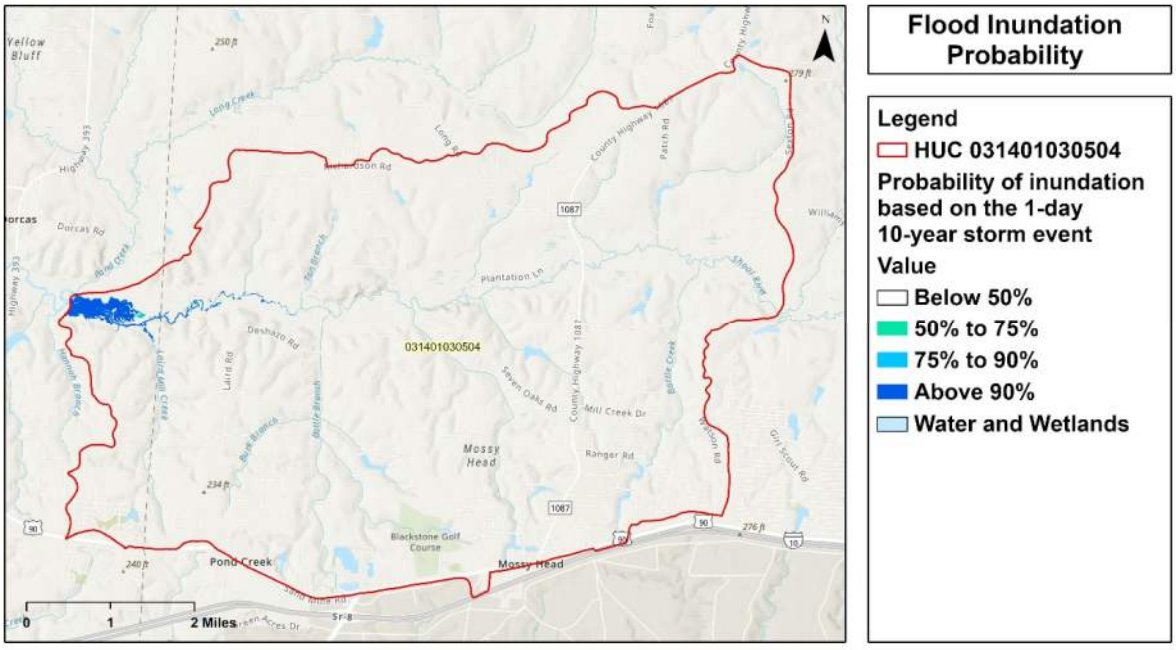

Figure 33. 1-day 10-year storm event for HUC 031401030504 sub-watershed. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

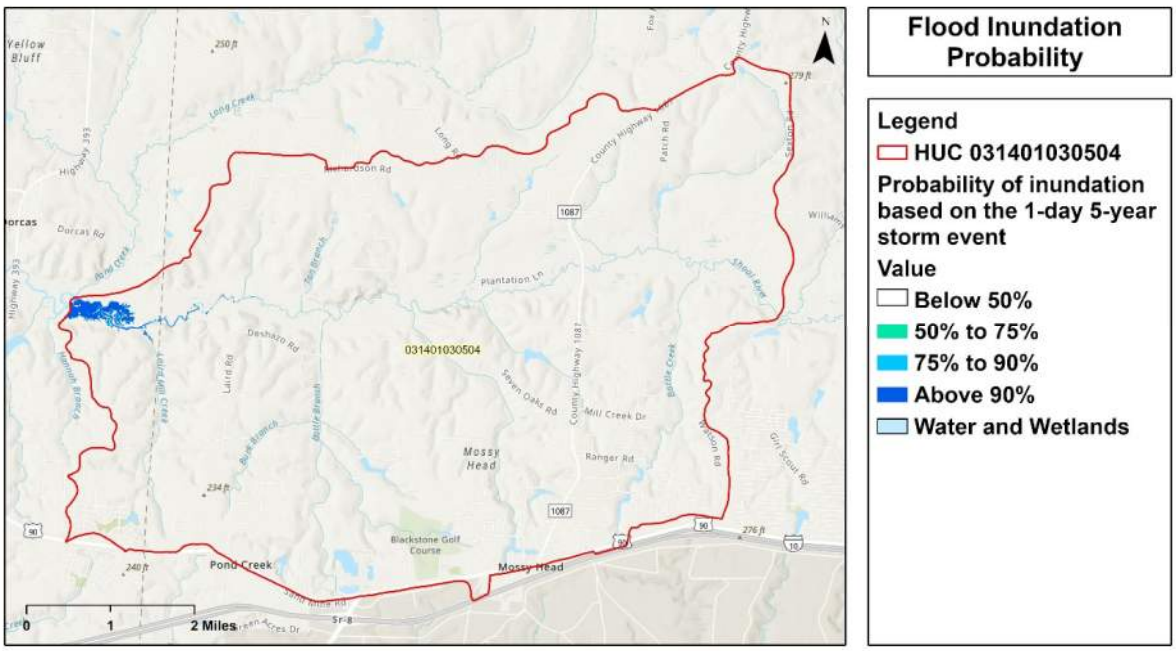

Figure 34. 1-day 5-year storm event for HUC 031401030504 sub-watershed. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401020504 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (

Figure 36) overlays critical facilities onto the 1-day 100-year storm event scenario.

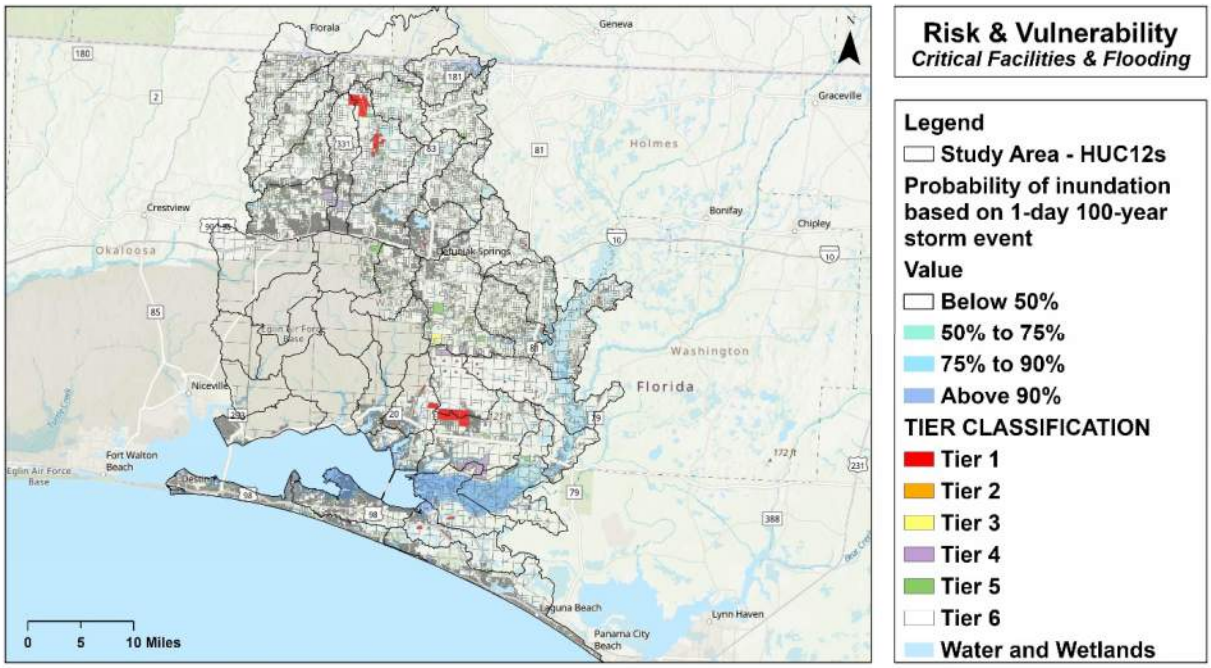

Figure 37 is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally,

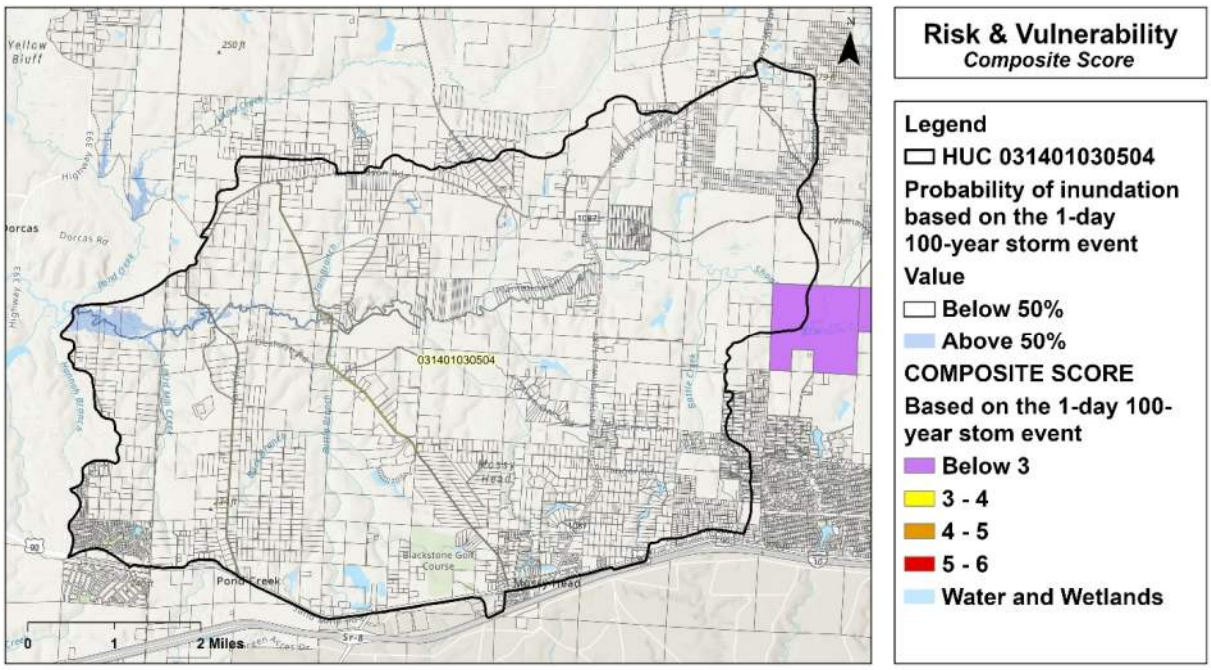

Figure 38 illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly,

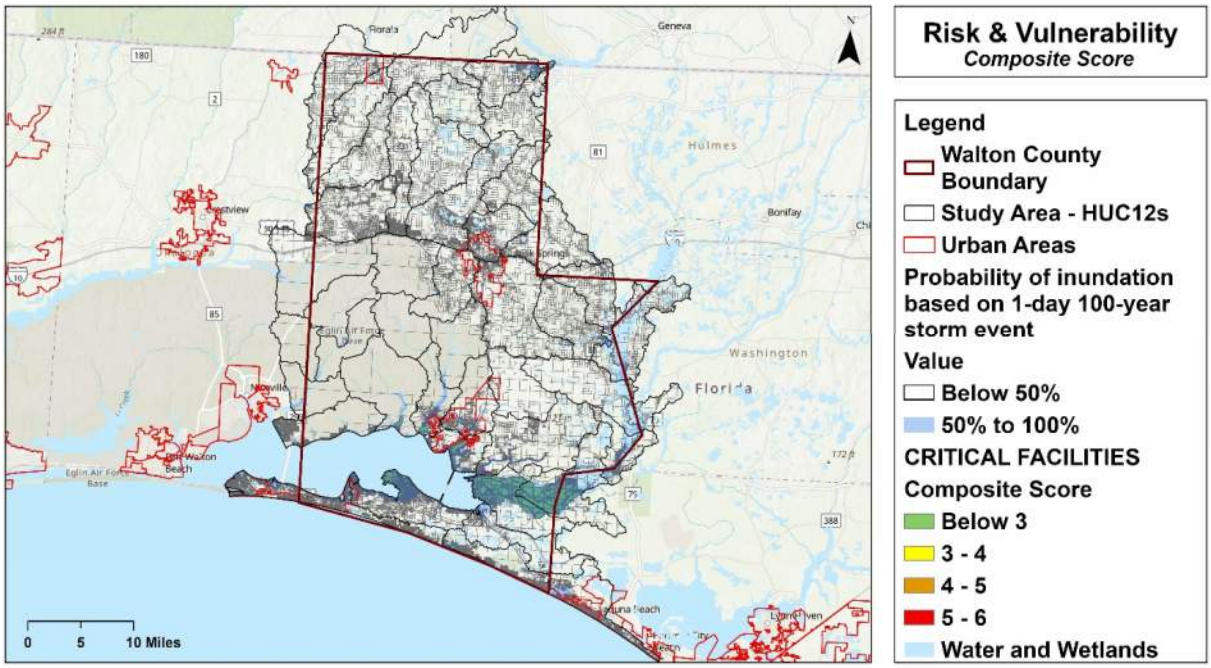

Figure 39 is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

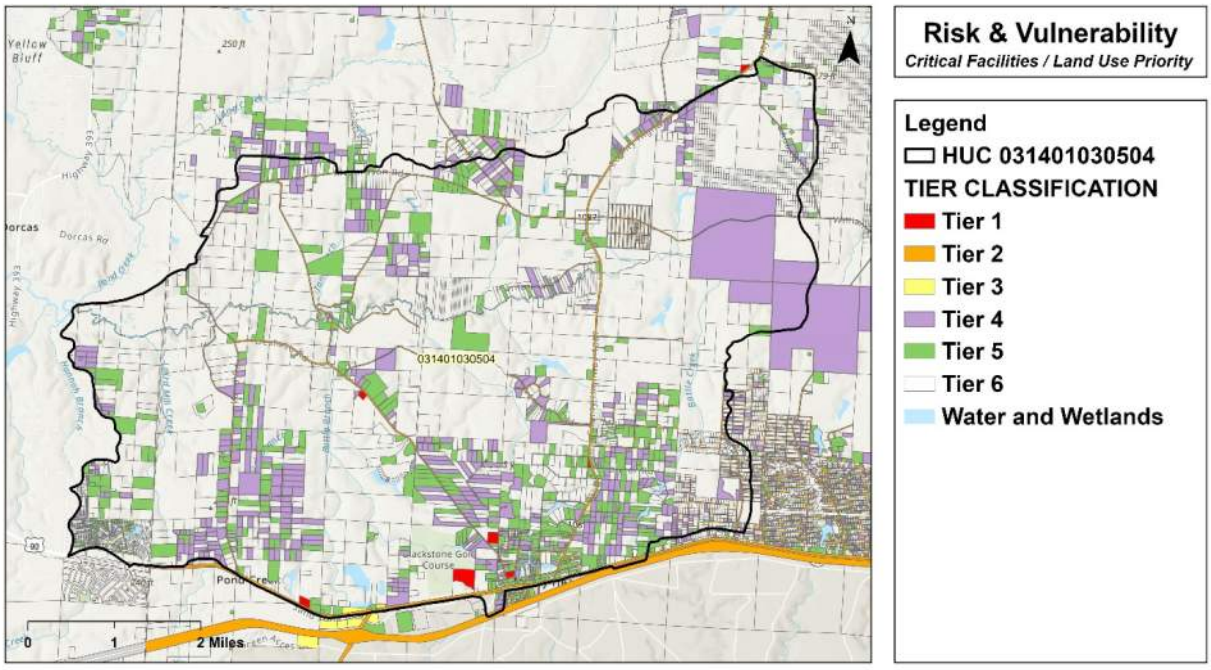

Figure 35. HUC 031401020504 sub-watershed Critical Facilities (priority of land uses) map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030504. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030504.Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030504	24308.00
All of the 1-day 100-year storm event inundation	**227.83**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	227.83
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	227.83

2.4.4 Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. . **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, displaying the estimated probability of repetitive loss.

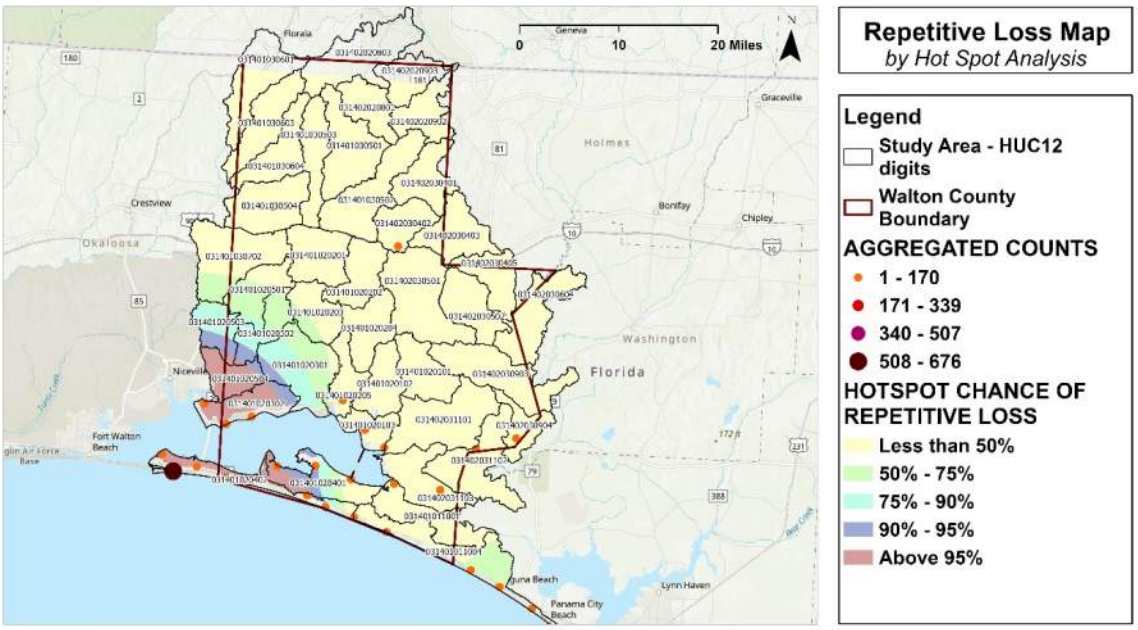

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are a few parcels falling within classification tier 1, and a good amount of parcels falling within tiers 4 and 5 of priority of land uses, only two of them are within the flooding zone, once flooding in the area is relatively minor and not alarming. Consequently, when considering the composite score, it is notable that there is only one parcel which is an orphanage or other non-profit or charitable services, situated within the flooding zone that need some attention, although it has a score below 3, indicating a low priority for intervention.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day, 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030601) is highlighted among all the HUCs to help identifying its location. (Figure 3).

A small town, Paxton, shares a portion of its boundary with the basin. Demographic data and other characteristics of Paxton, along with other cities in Walton County, will be discussed later.

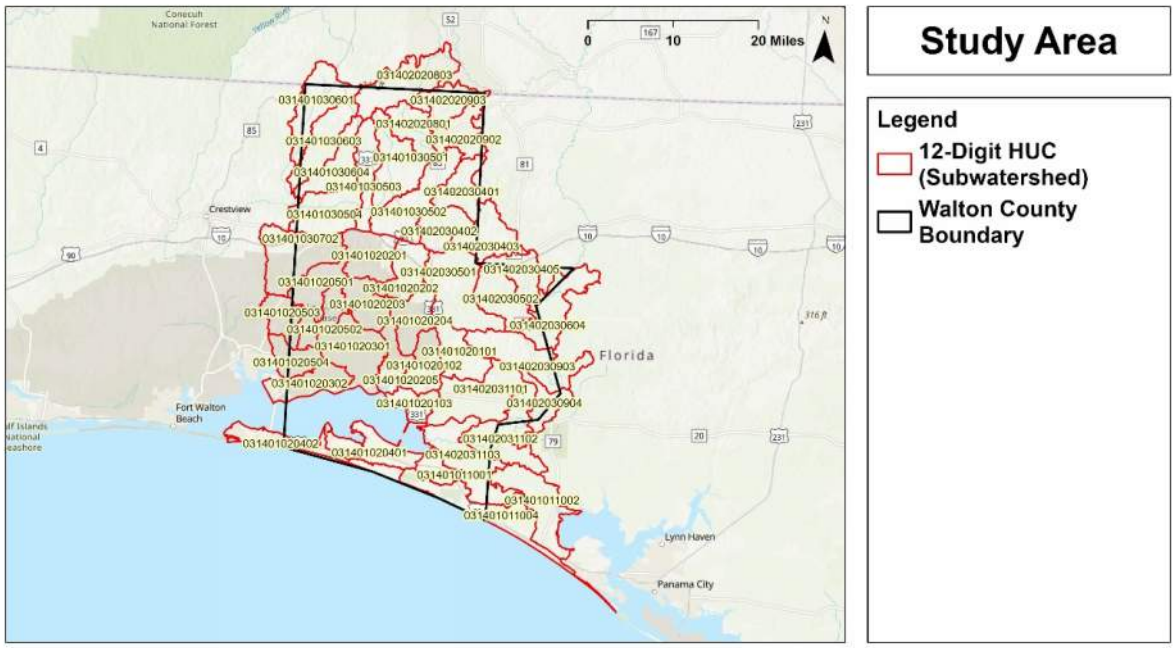

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

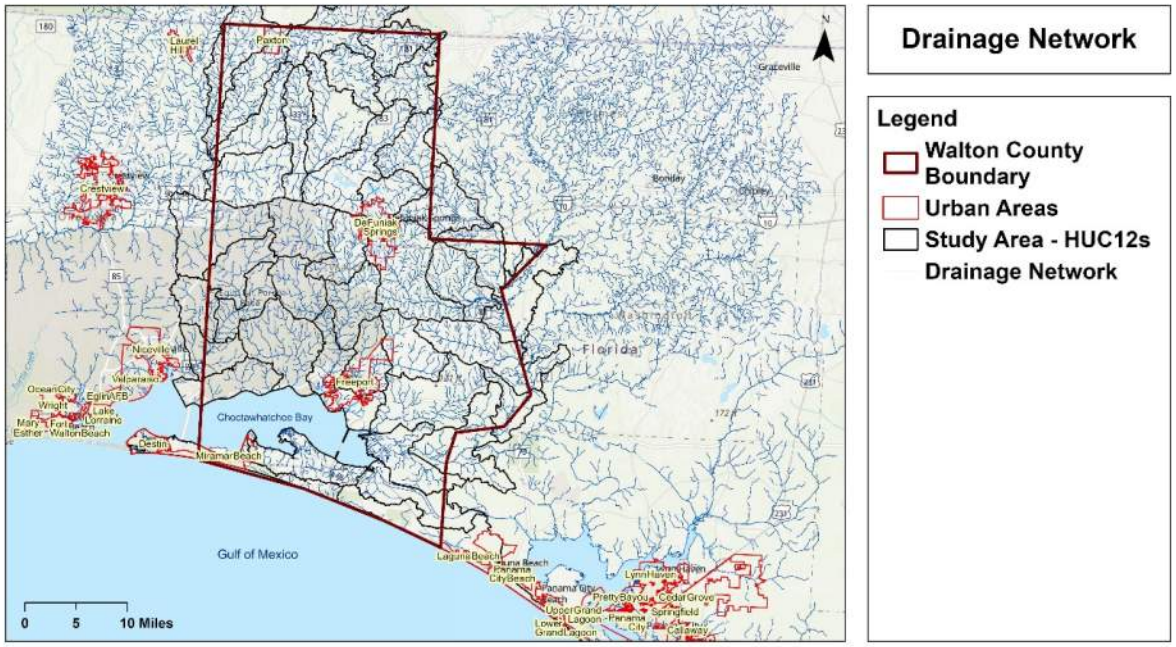

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

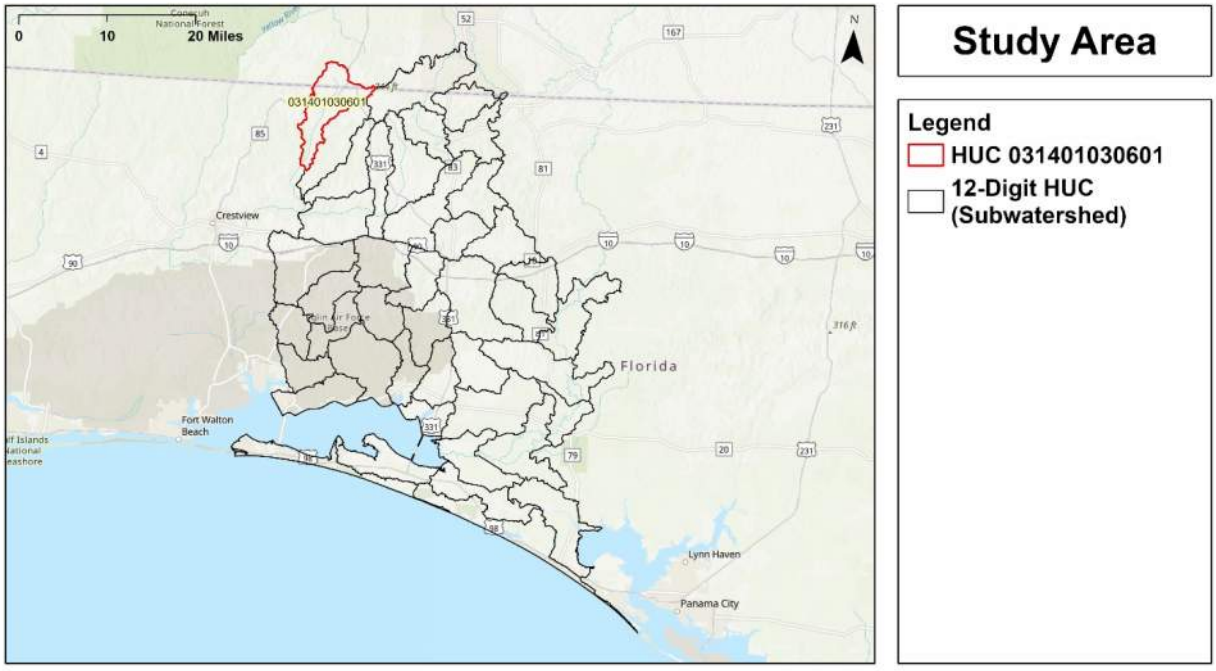

Figure 3. HUC 031401030601 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

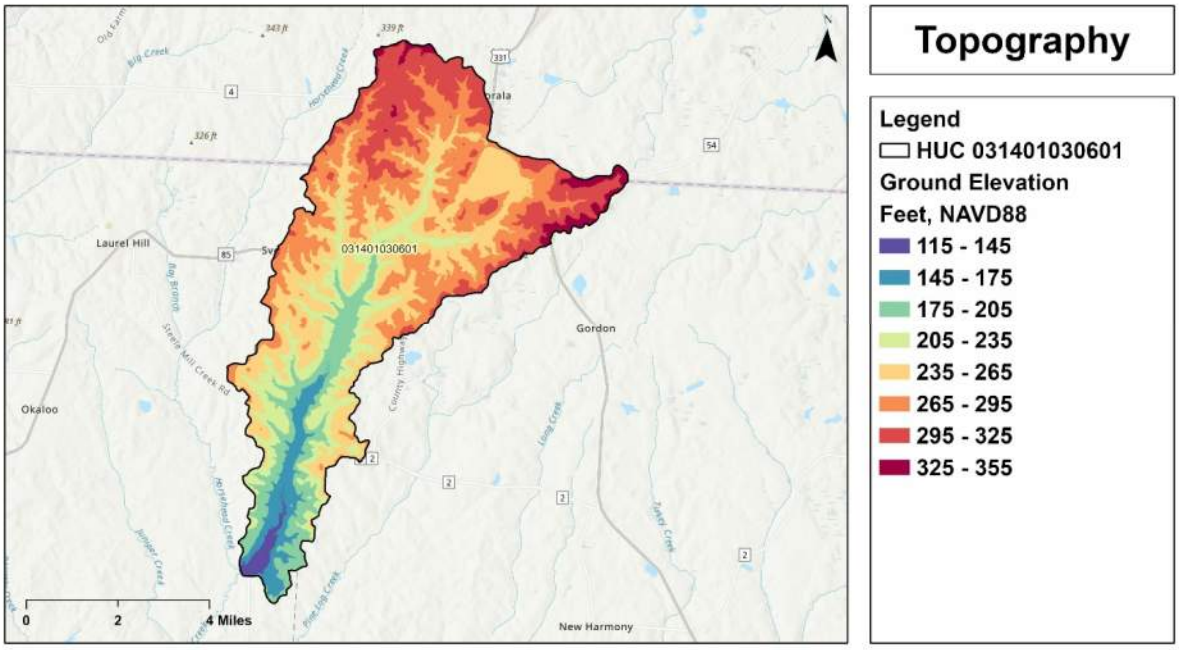

Figure 4. Topographic map of the HUC 031401030601 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030601 sub-watershed is shown in **Error! Reference source not found.**.

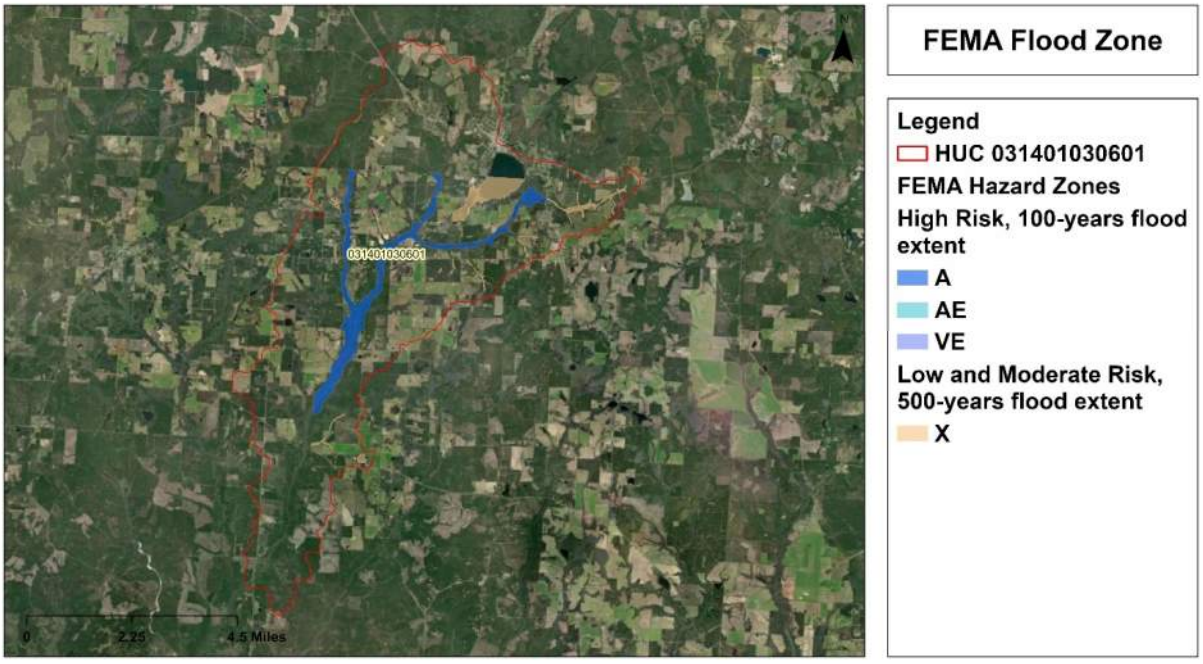

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030601 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination

between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030601 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

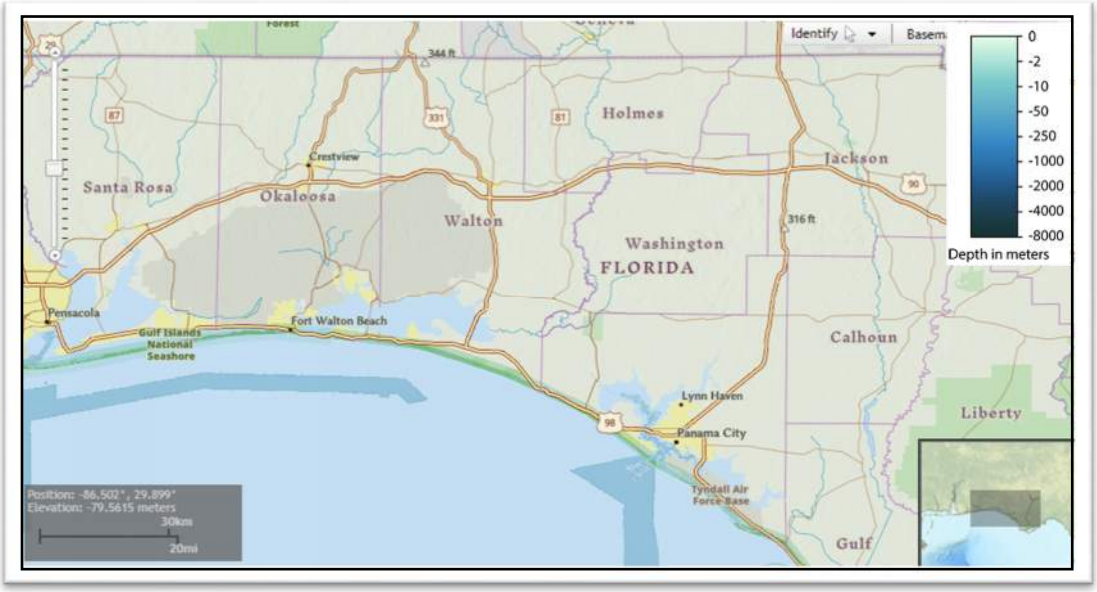

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

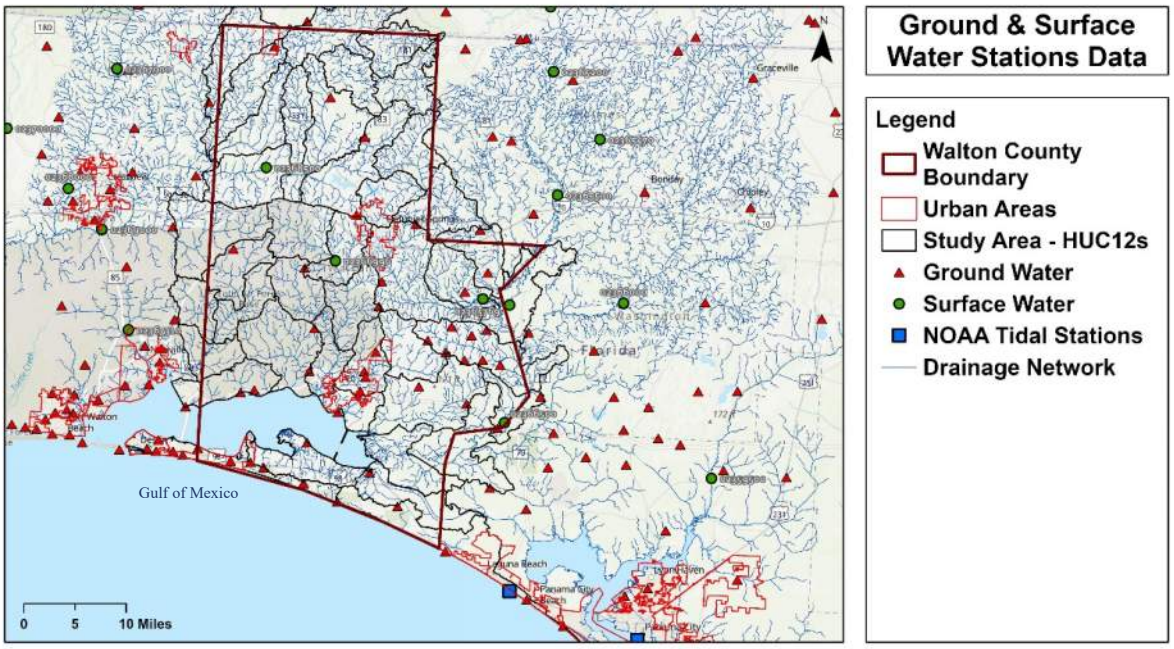

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030601 has no major rivers and canals, but creeks, incude:

- Pond Creek
- Fleming Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030601, which is USGS 02368500 Shoal River.

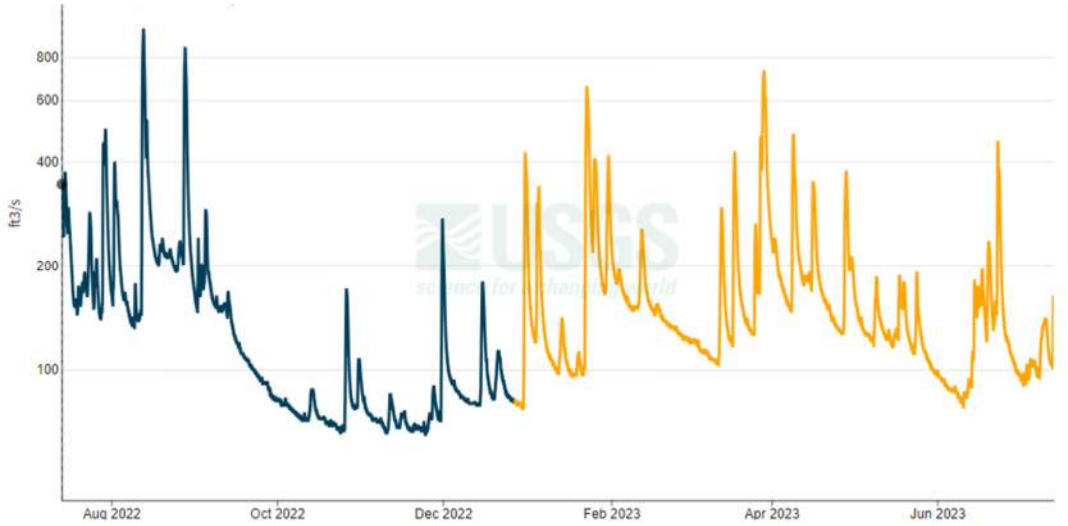

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030601 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401020101 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

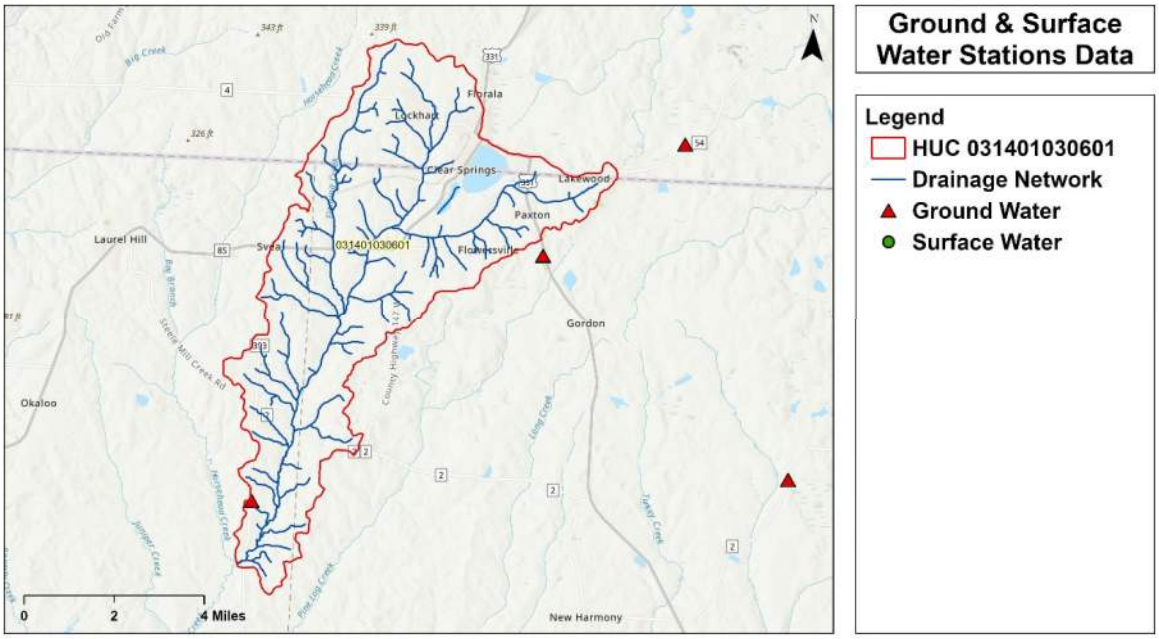

Figure 9. Ground and Surface Water Stations in the HUC 031401030601 sub-watershed, processed by FAU.

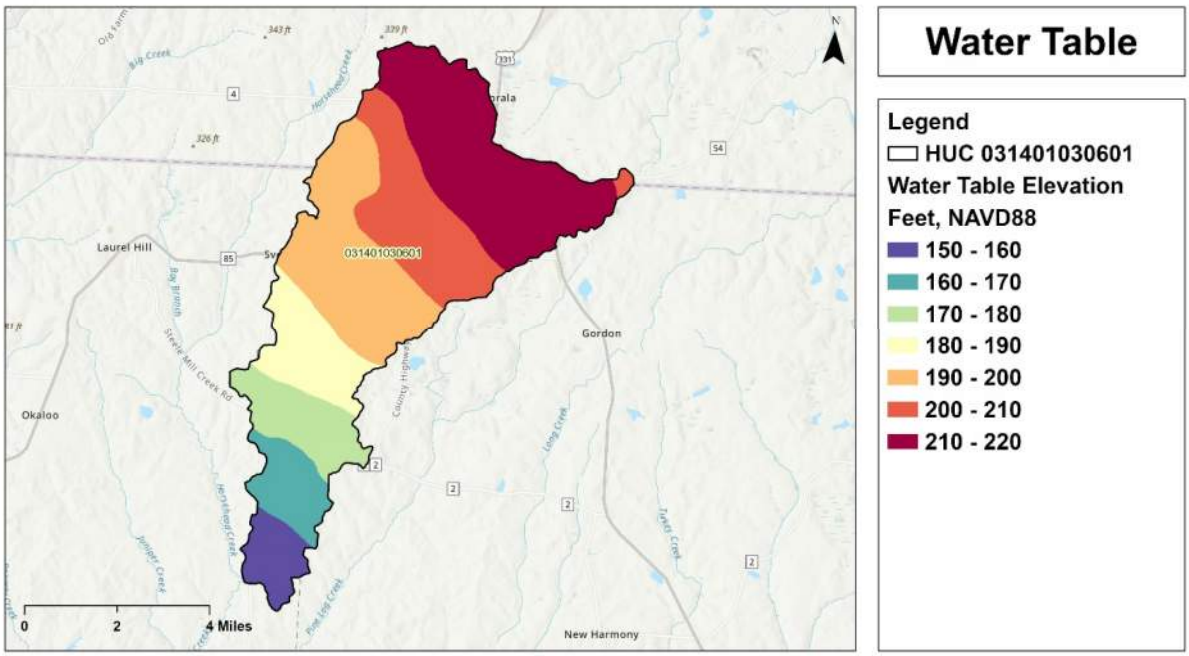

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030601 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

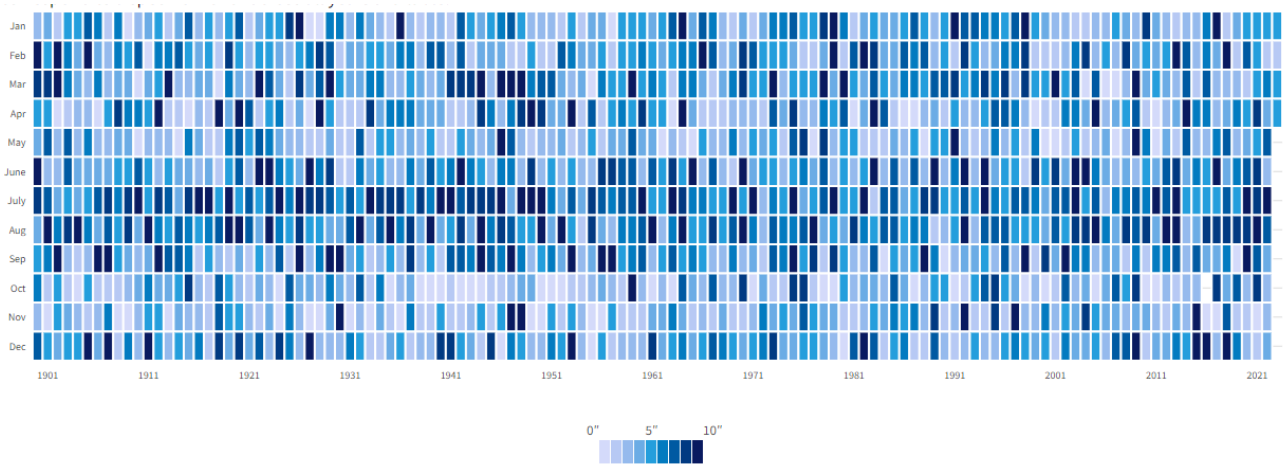

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

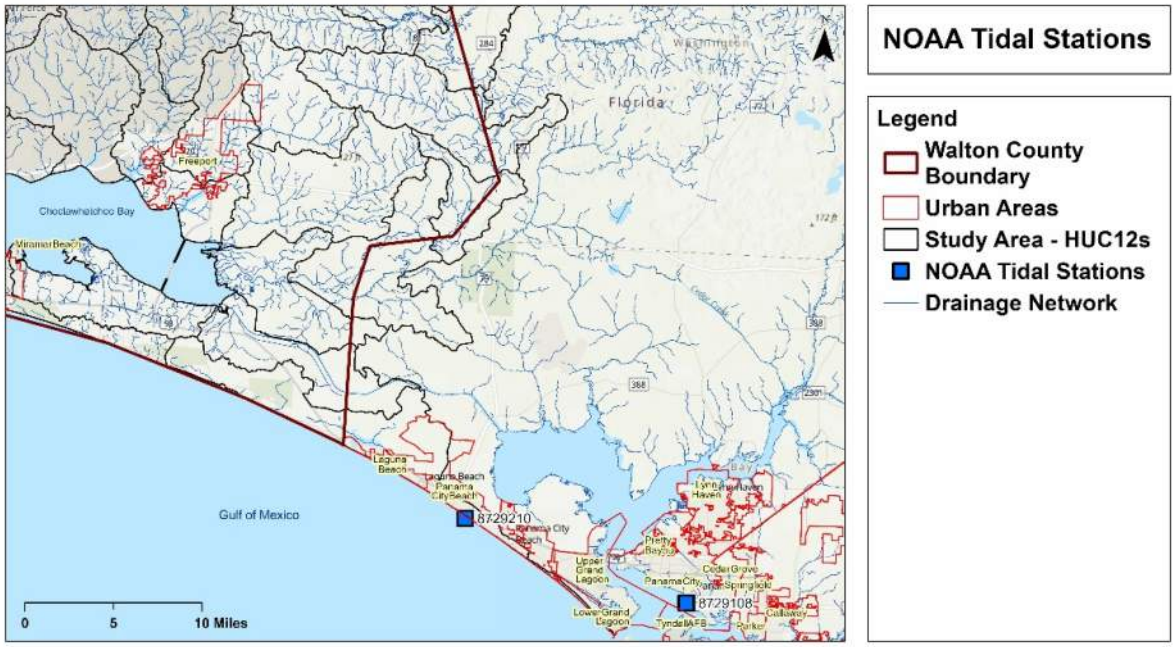

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

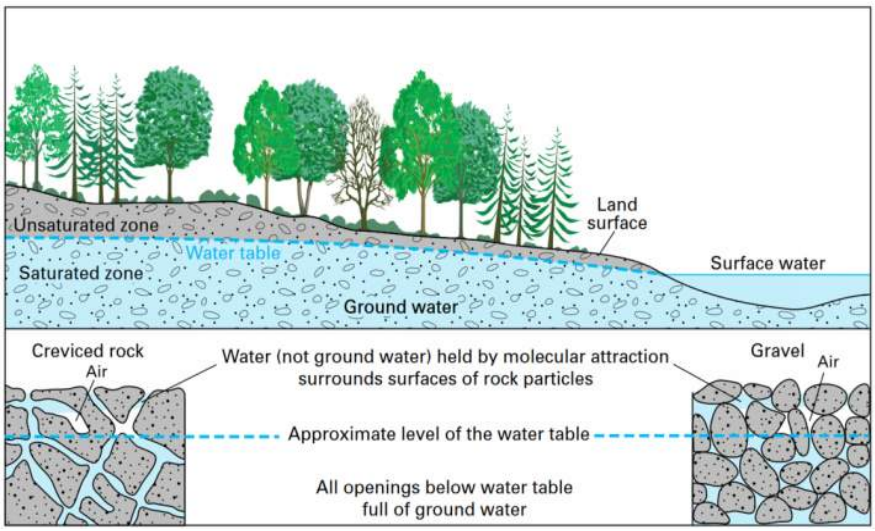

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

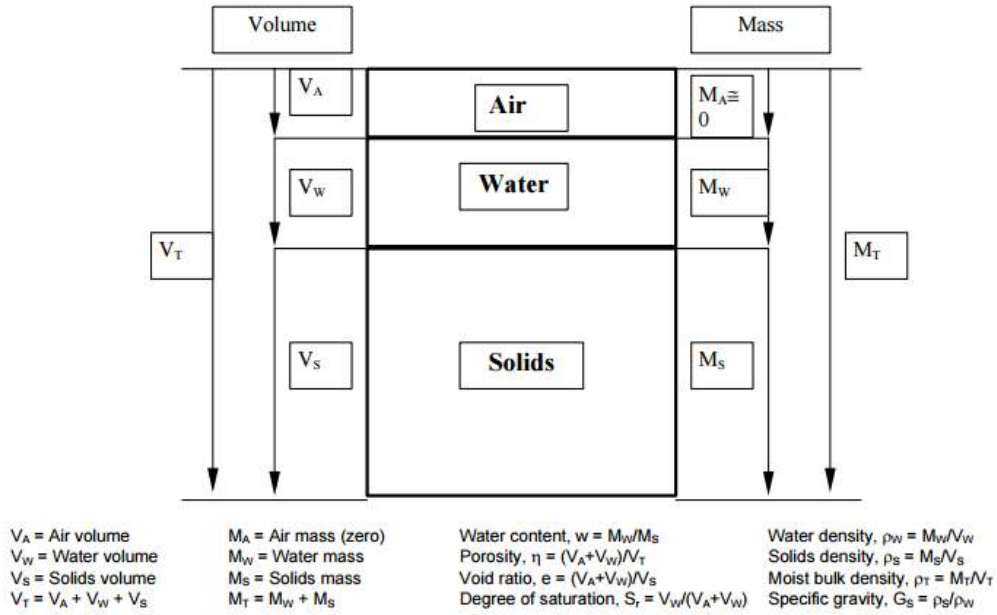

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

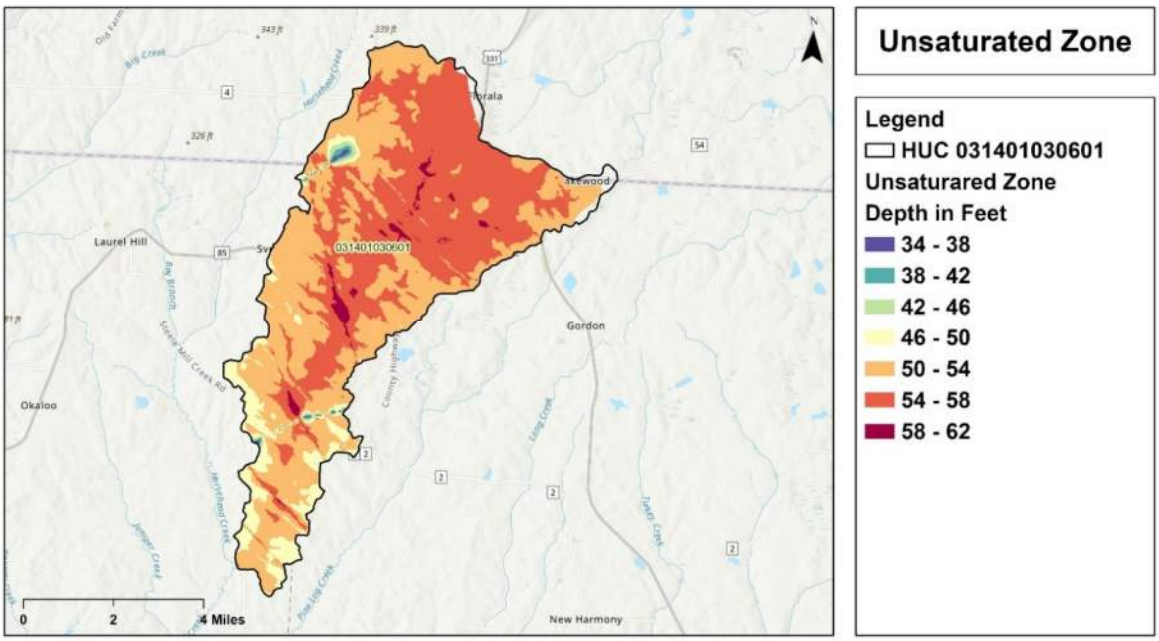

Figure 15. Unsaturated zone map for HUC 031401030601, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A great portion of the basin has enough soil storage capacity, ranging between 50 to 58 inches of capacity left.

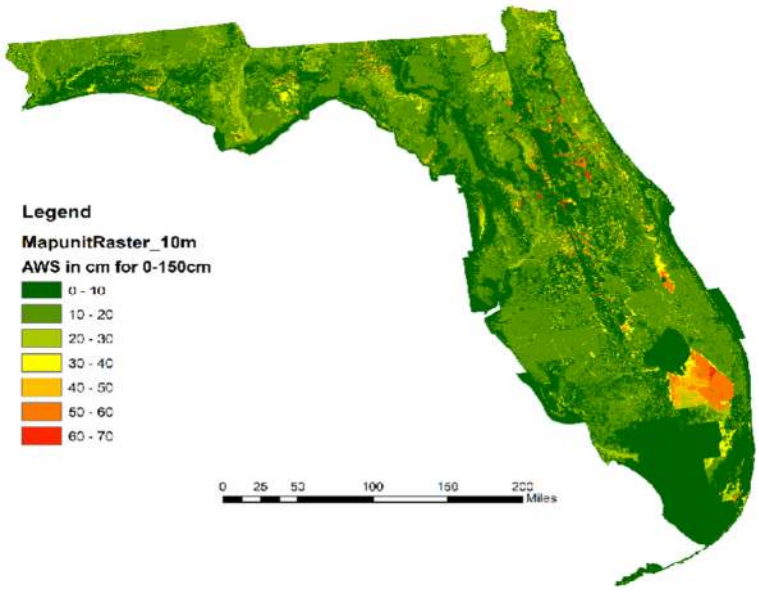

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

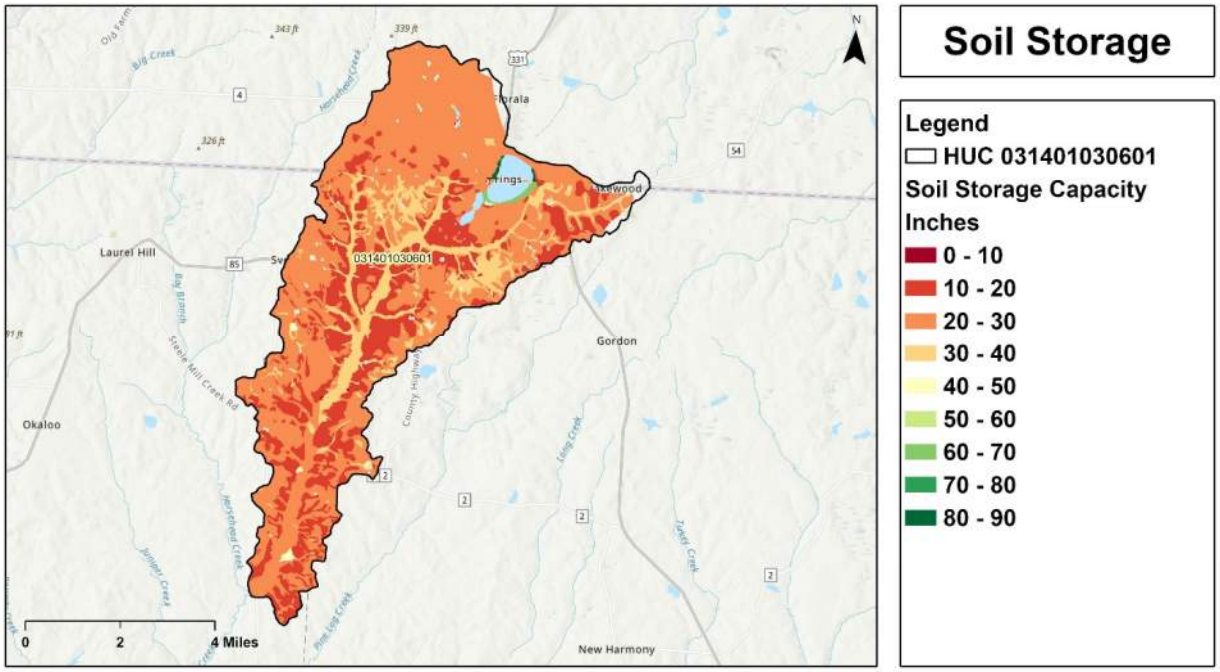

Figure 17. Water storage capacity of soil for the HUC 031401030601, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

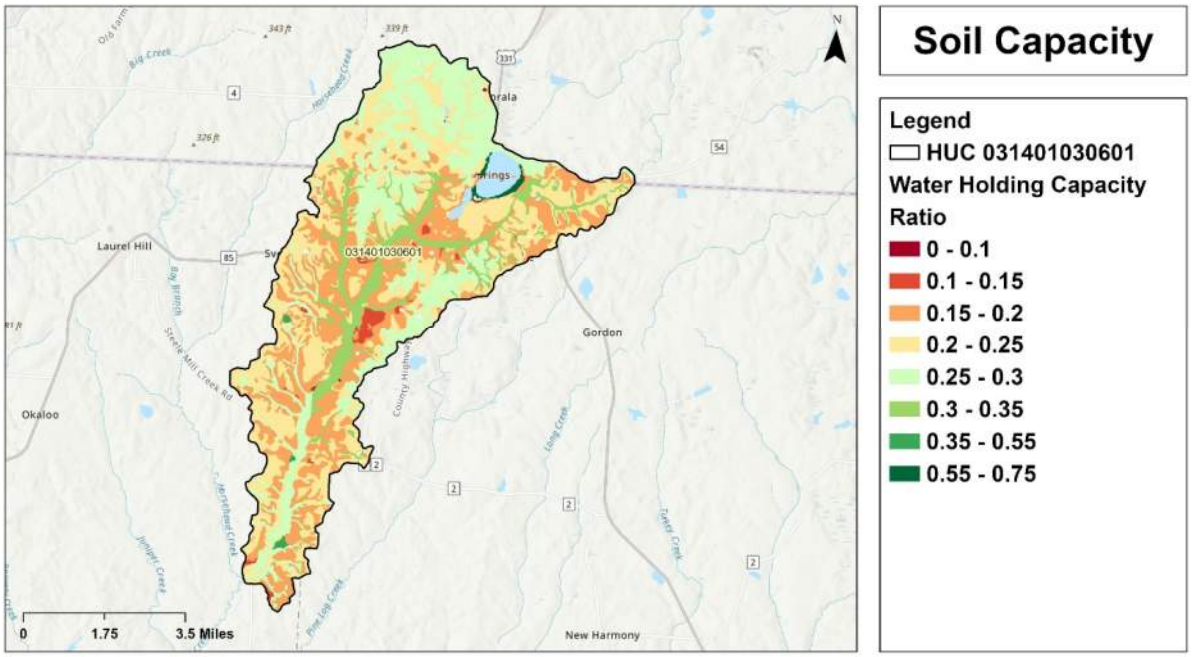

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030601, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

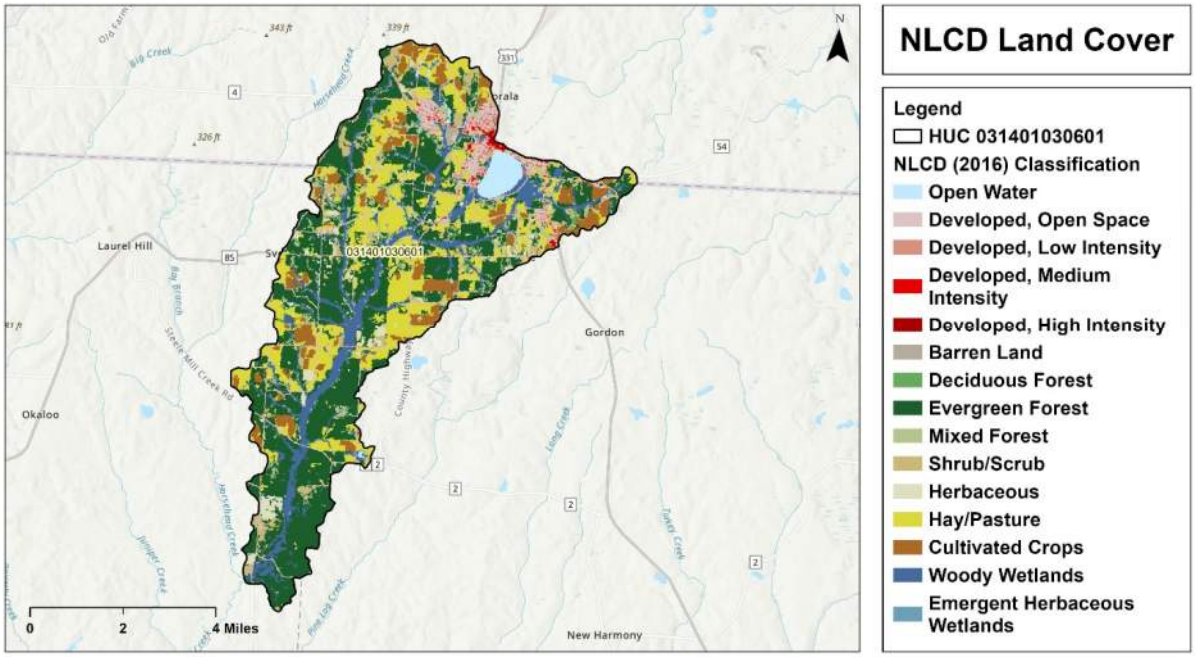

Figure 19. Land use in the HUC 031401030601 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

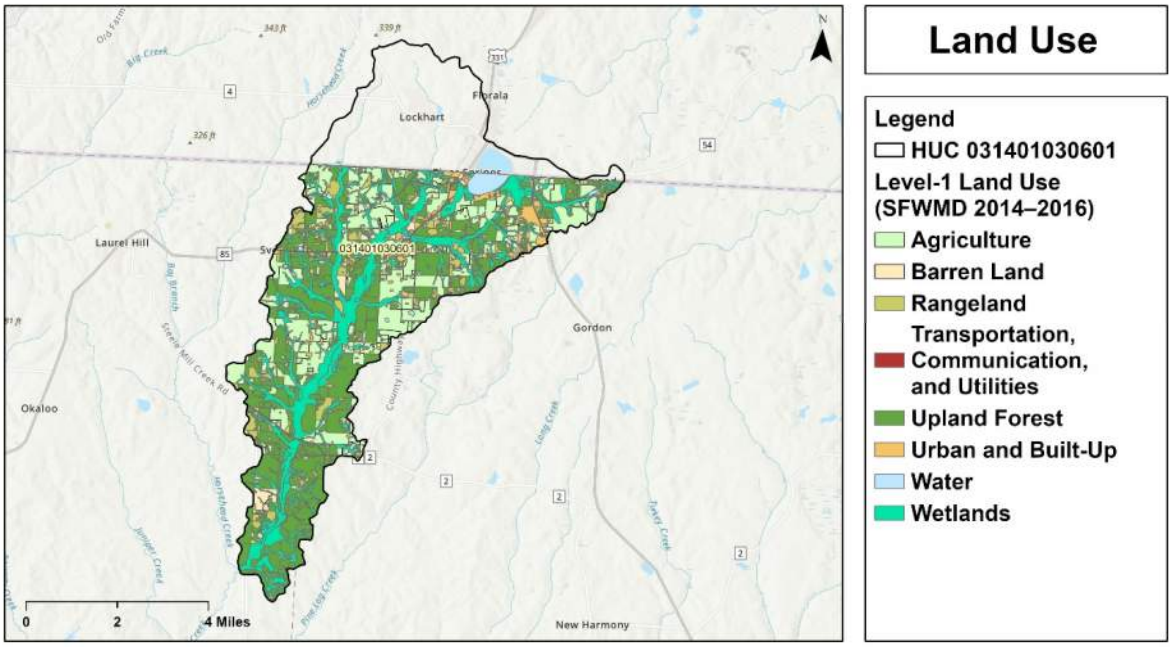

Figure 20. Land use in the HUC 031401030601 (2023 Florida Geographic Data Library (FGDL))), processed by FAU.

Please be aware that the Alabama portion of the HUC was not considered in this land use study. Consequently, the following analysis pertains solely to the Florida portion of the HUC 031401020101 sub-watershed. In this area, the predominant land cover is upland forest, accounting for 40.97% of the region. Agriculture comes in second at 24.77%, followed by wetlands at 18.85%. Developed land is limited, with only 5.16% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030601 subwatershed (2023 Florida Geographic Data Library (FGDL))).

Level 1 Land Use Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	5403.27	24.77%
Barren Land	249.58	1.14%
Rangeland	1023.75	4.69%
Transportation, Communication, and Utilities	252.61	1.16%
Upland Forest	8937.82	40.97%
Urban and Built-Up	1125.86	5.16%
Water	712.79	3.27%
Wetlands	4111.81	18.85%
Grand Total:	**21817.49**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day, 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

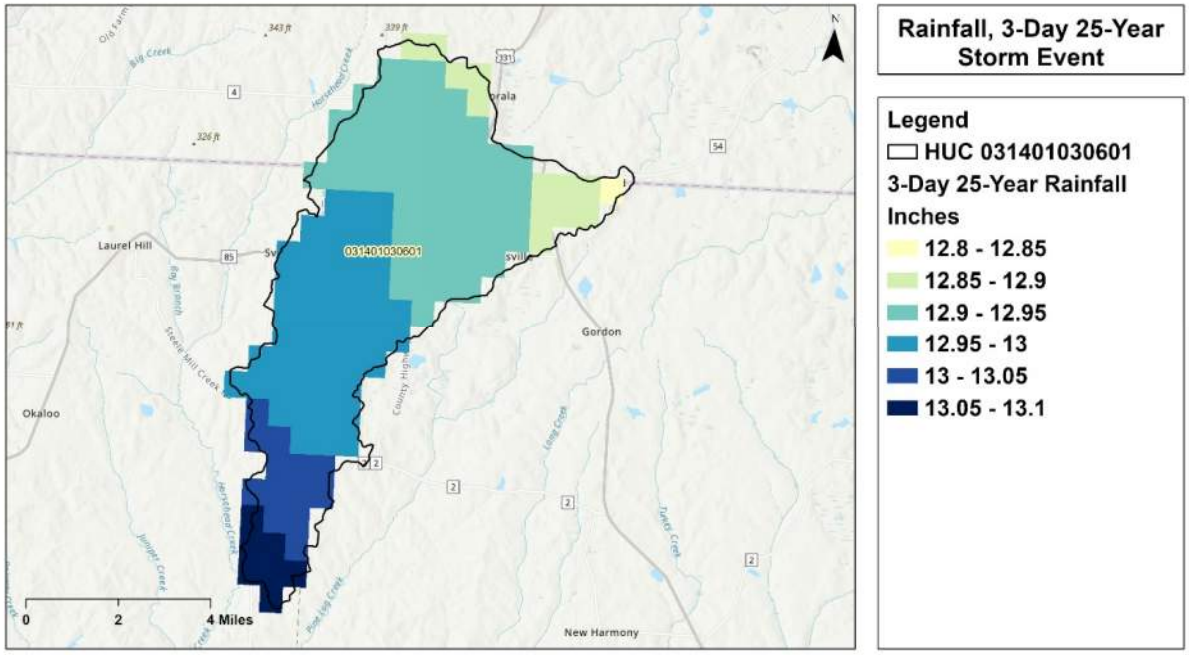

Figure 21. Rainfall distribution map across HUC 031401030601 sub-watershed, for 3-day 25-year storm event, processed by FAU.

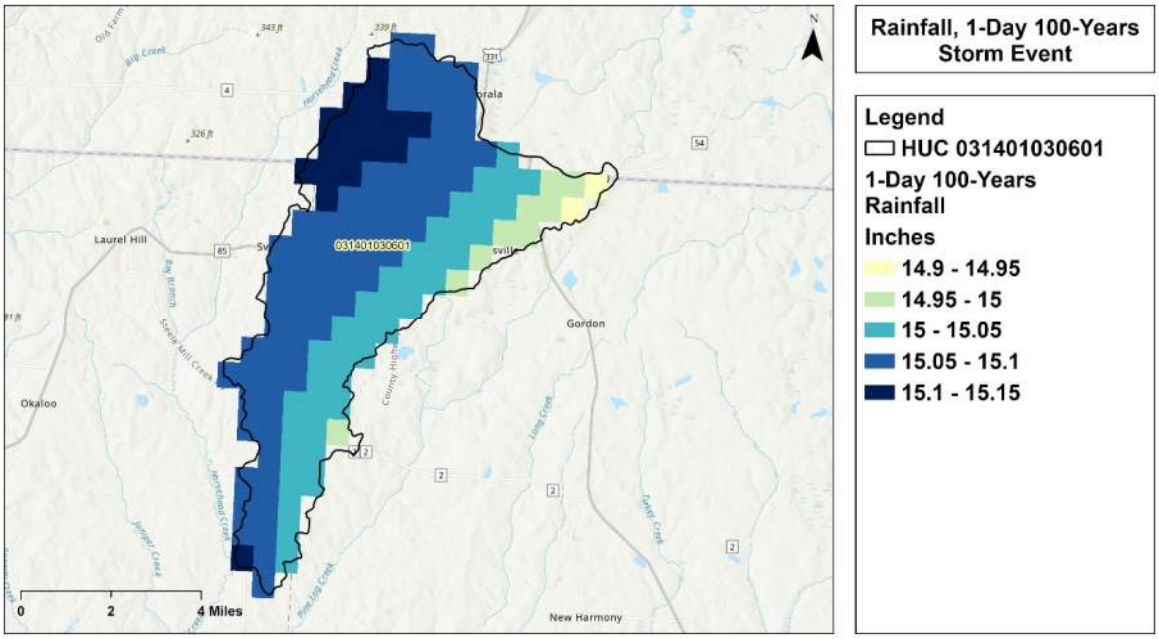

Figure 22. Rainfall distribution map across HUC 031401030601 sub-watershed, for 1-day 100-year storm event, processed by FAU.

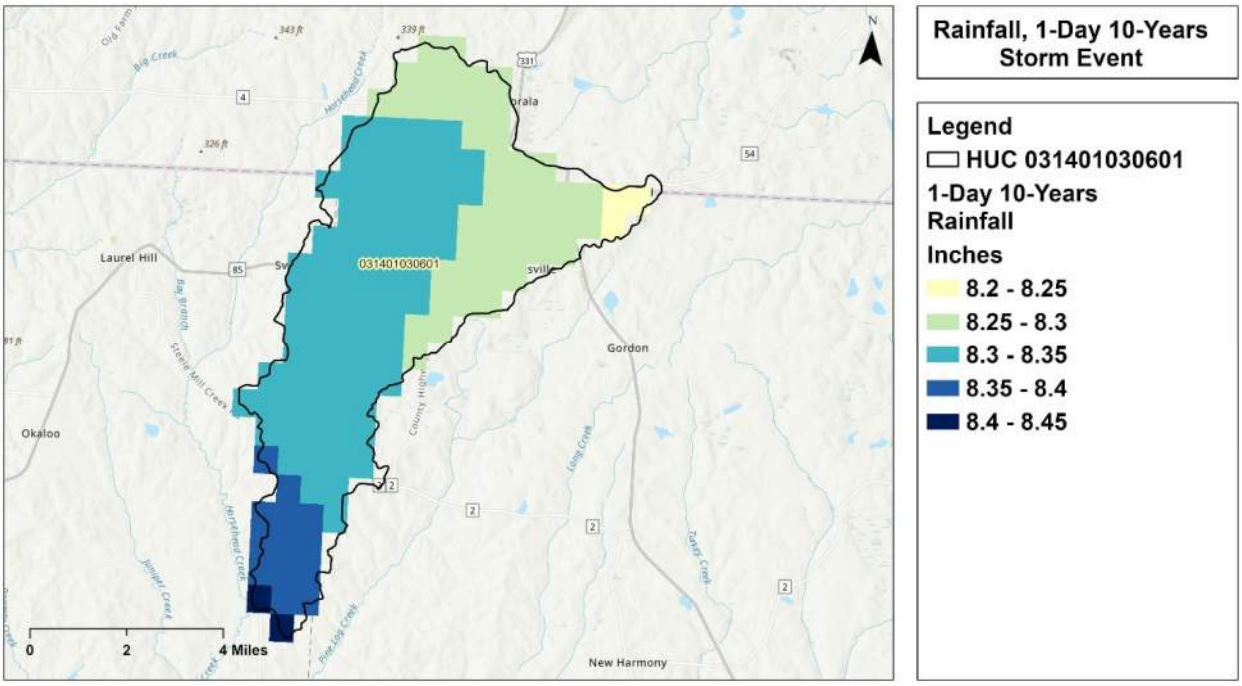

Figure 23. Rainfall distribution map across HUC 031401030601 sub-watershed, for 1-day 10-year storm event, processed by FAU.

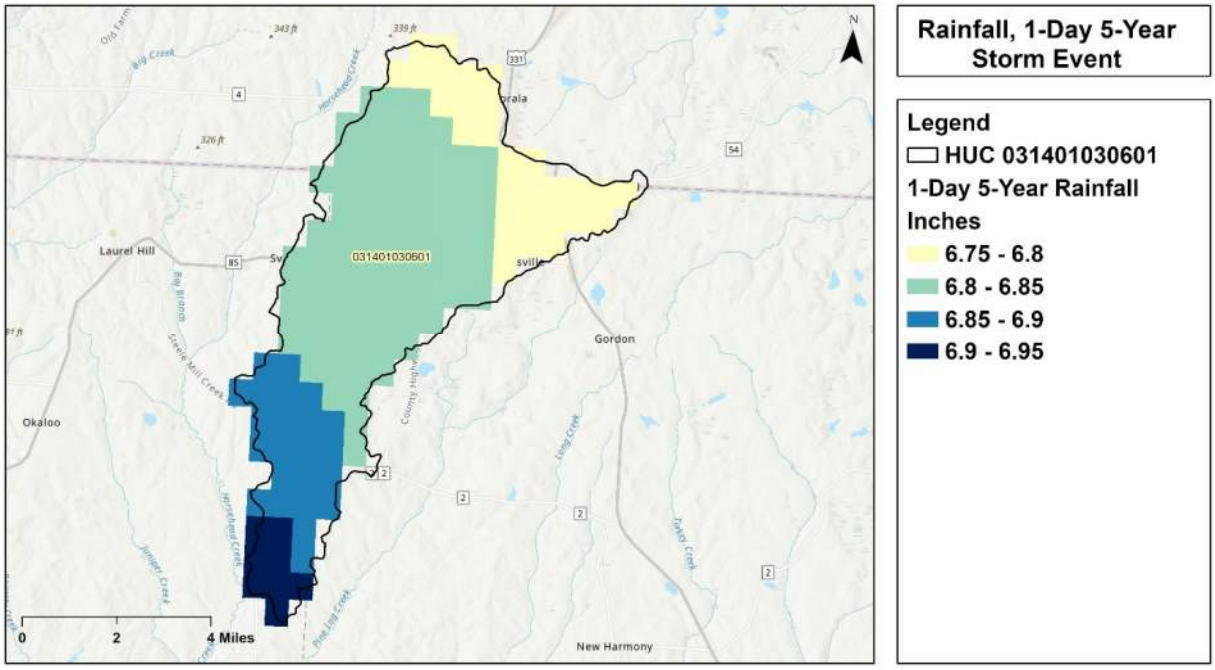

Figure 24. Rainfall distribution map across HUC 031401030601 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically

aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

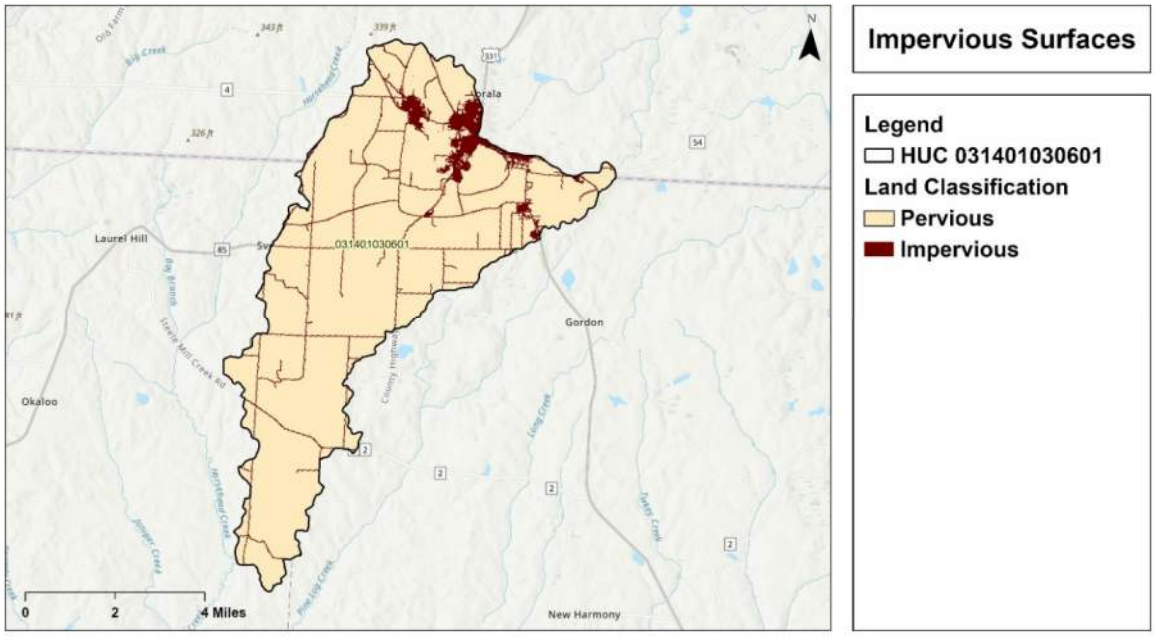

Figure 25. Impervious area map for the HUC 031401030601 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

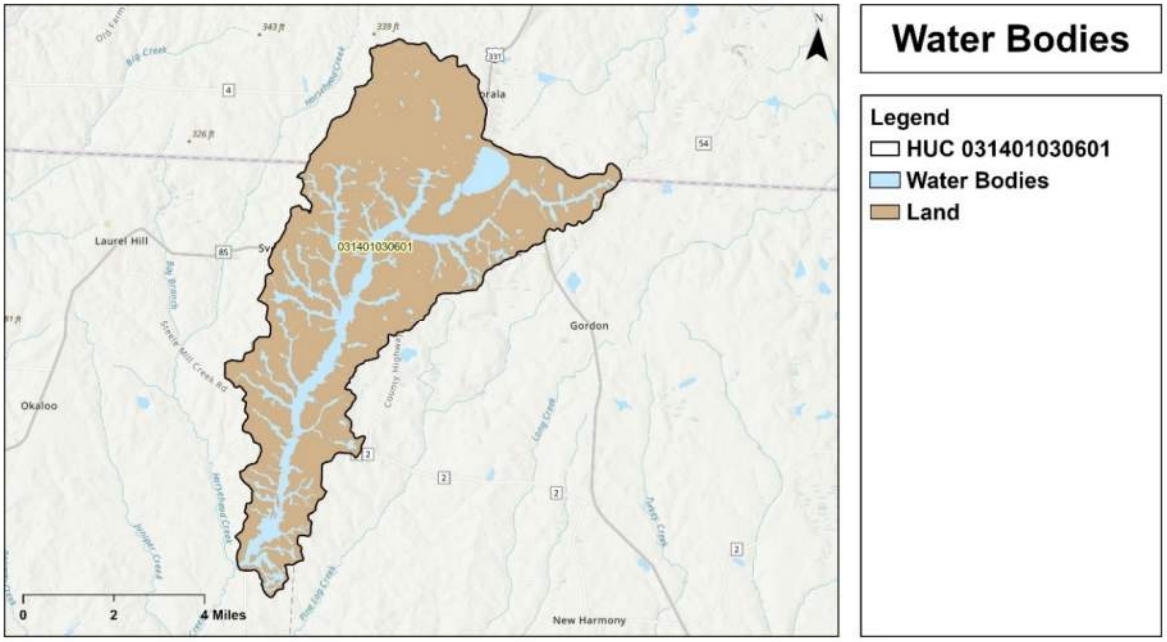

Figure 26. Water bodies map for the HUC 031401030601 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs,

property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, , such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

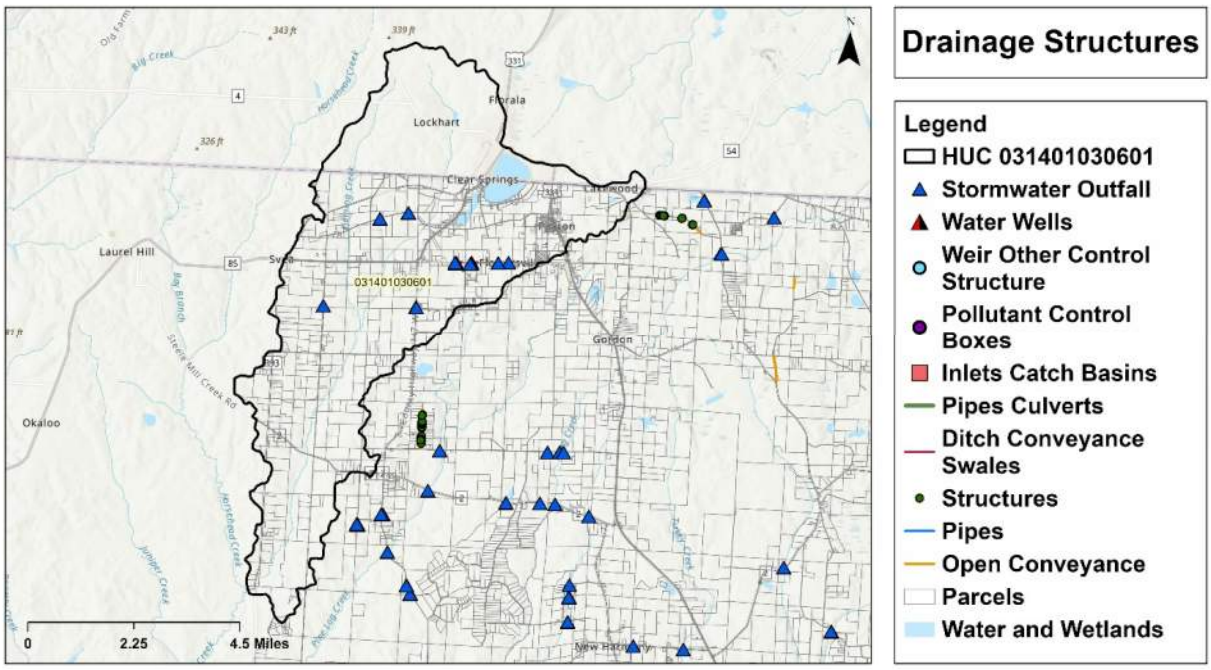

Figure 27. Stormwater Infrastructure for the HUC 031401030601. Processed by FAU.

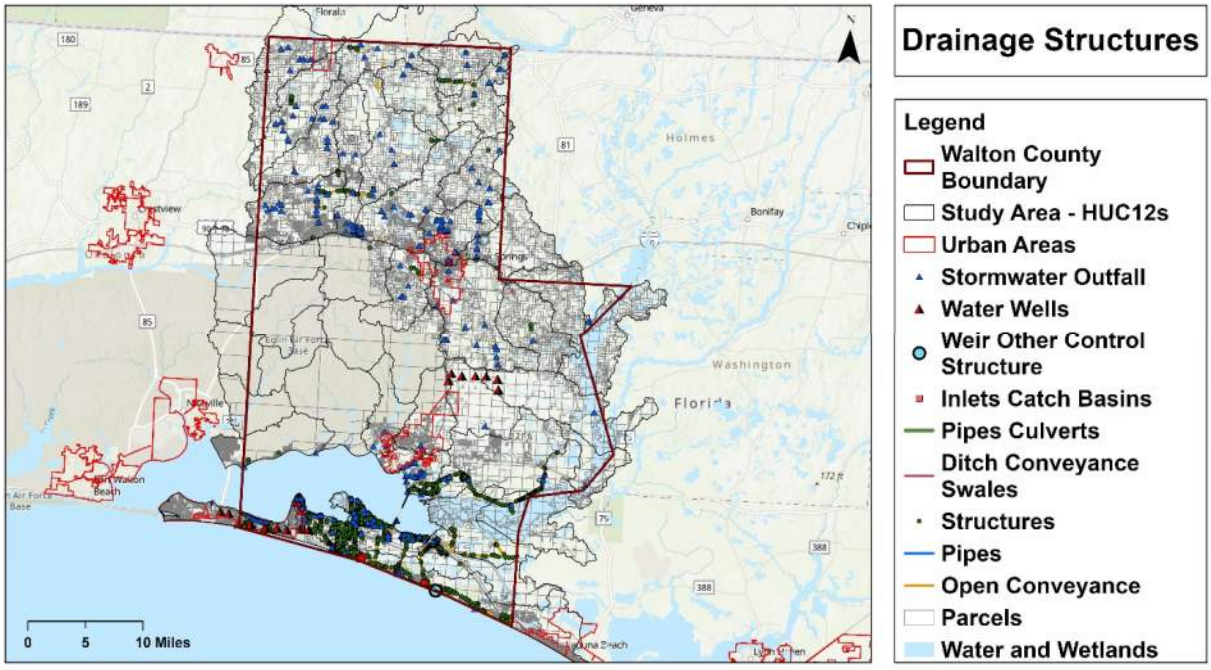

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030601 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

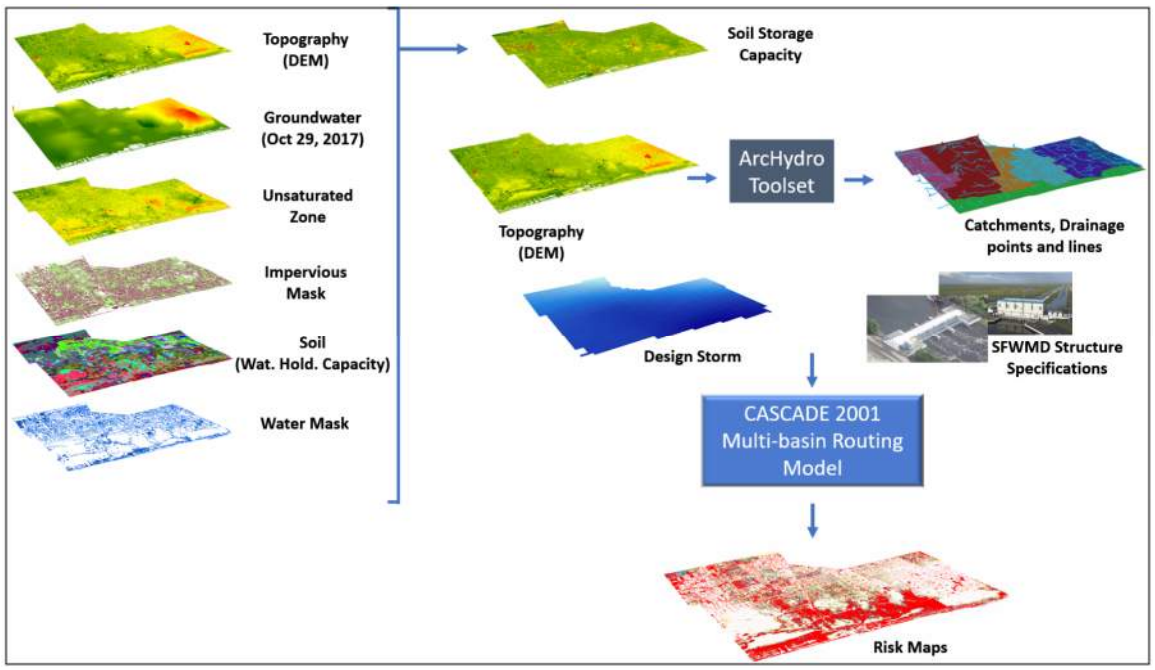

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

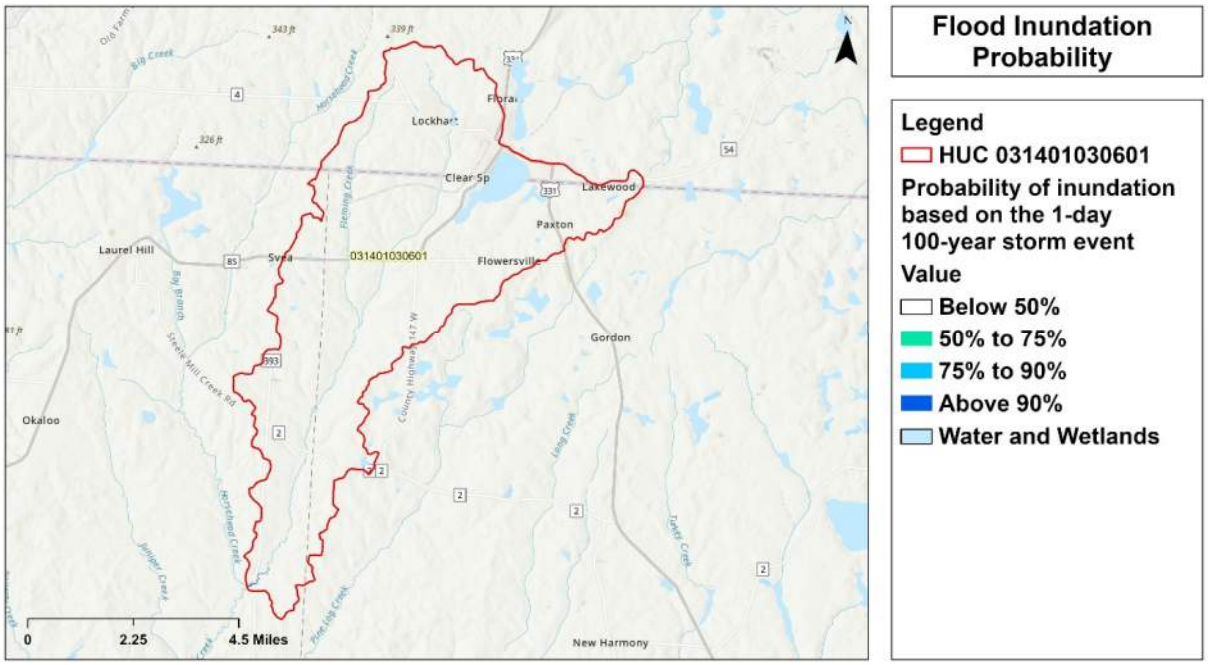

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030601, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation

and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations,

Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:In all storm event scenarios, a small portion of flooding, almost imperceptible, is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0% of the HUC total area or only 0.01 mi² has a probability of inundation above 50% for all four storm event scenarios. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030601 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	38.28	0.01	100.0%	0.0%
1-day 100-year	38.28	0.01	100.0%	0.0%
1-day 10-year	38.28	0.01	100.0%	0.0%
1-day 5-year	38.28	0.01	100.0%	0.0%

Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.**depict the HUC 031401030601 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

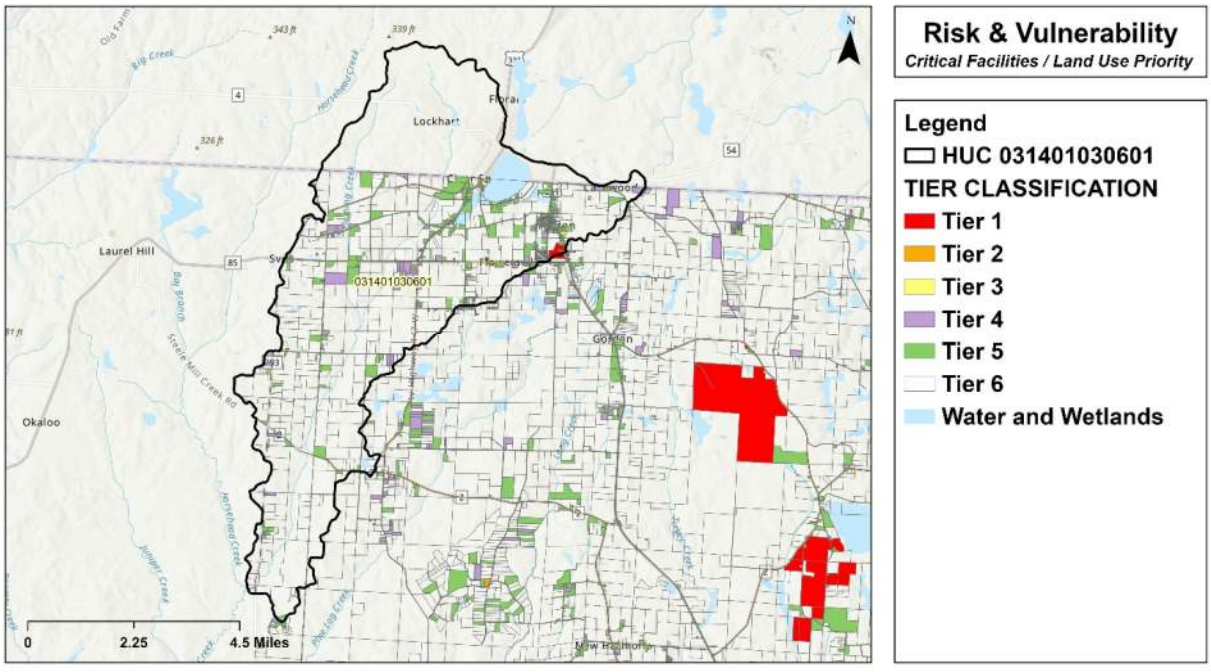

Figure 35. HUC 031401030601 sub-watershed Critical Facilities (priority of land uses) map. Processed by FAU.

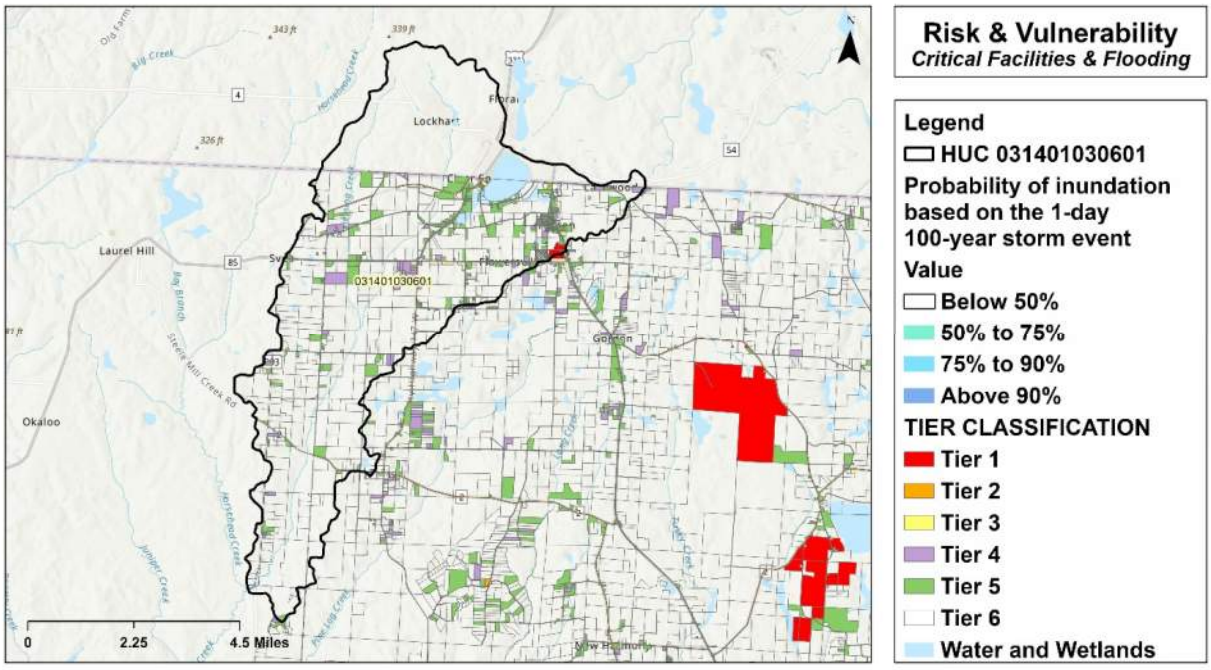

Figure 36. HUC 031401030601 sub-watershed Critical Facilities (priority of land uses) map overlaid on the 1-day, 100-year storm event probability of inundation. Processed by FAU.

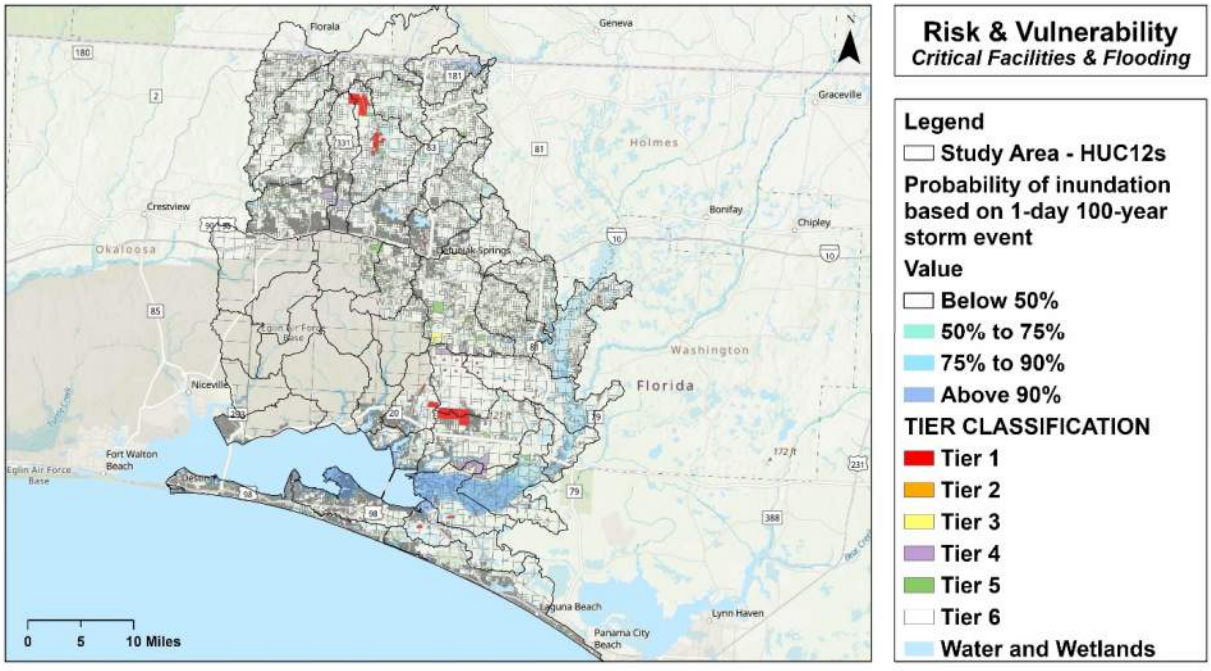

Figure 37. Walton County (mosaic) - Critical Facilities (priority of land uses) map overlaid on the 1-day, 100-year storm event probability of inundation for Walton County. Processed by FAU.

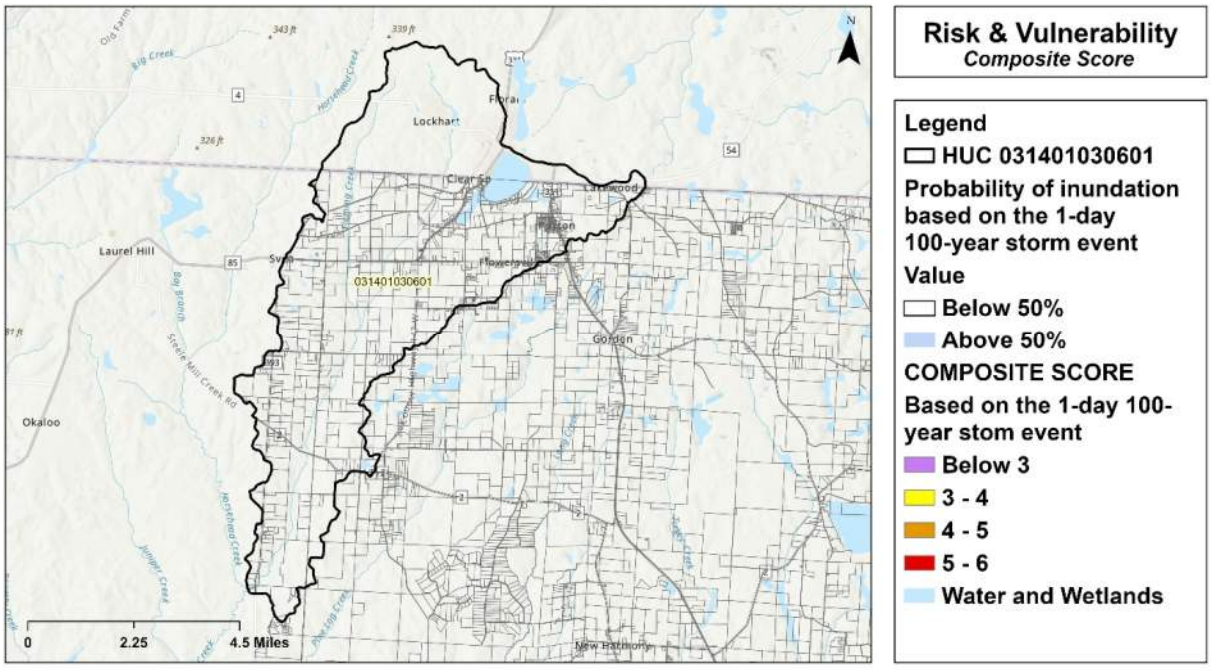

Figure 38. HUC 031401030601 sub-watershed Composite Score Risk map, with calculation based on 1-day 100-years storm event. Processed by FAU.

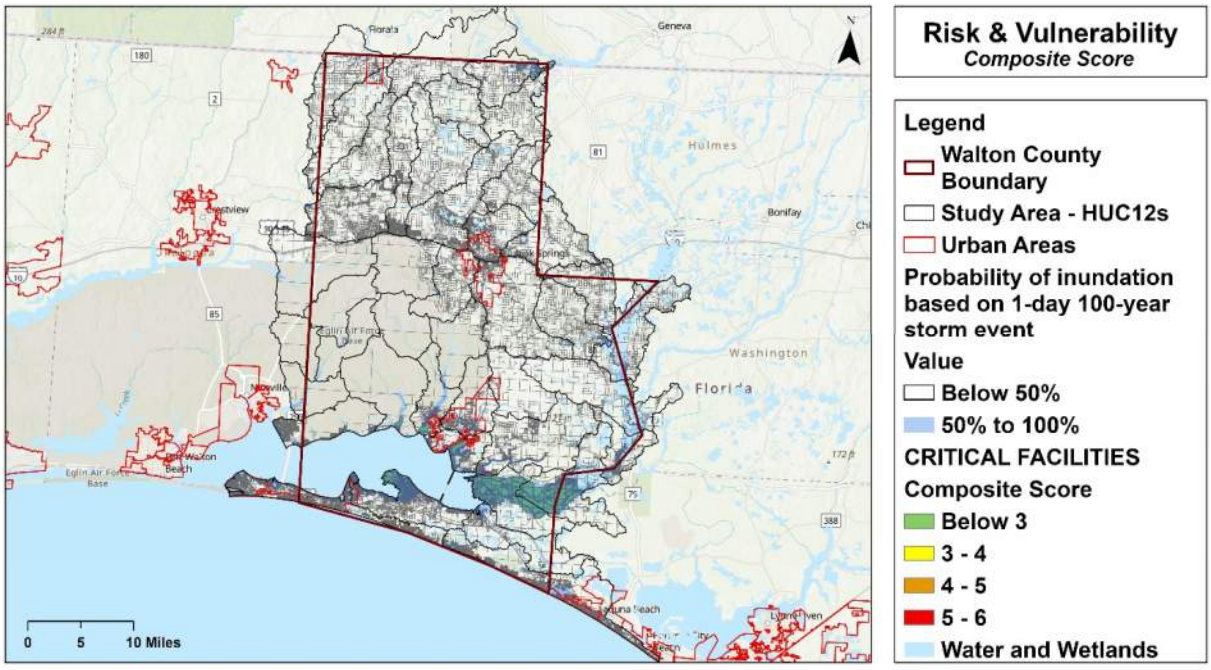

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day, 100-year storm event probability of inundation. Processed by FAU.
Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.4.2 Drill-down – Paxton

For enhanced visualization of the urban areas within this HUC 031401030601, **Error! Reference source not found.** to **Error! Reference source not found.** illustrate the same results for critical facilities (land use priorities) and composite scores, but on a reduced scale, which better facilitates the examination of finer details within the urban area (Paxton). These maps cover both the 1-day 100-year scenario. Sea level rise scenarios were not calculated due to the basin's non-coastal location and high elevation. The composite score results is null, since the town does not experience any flooding.

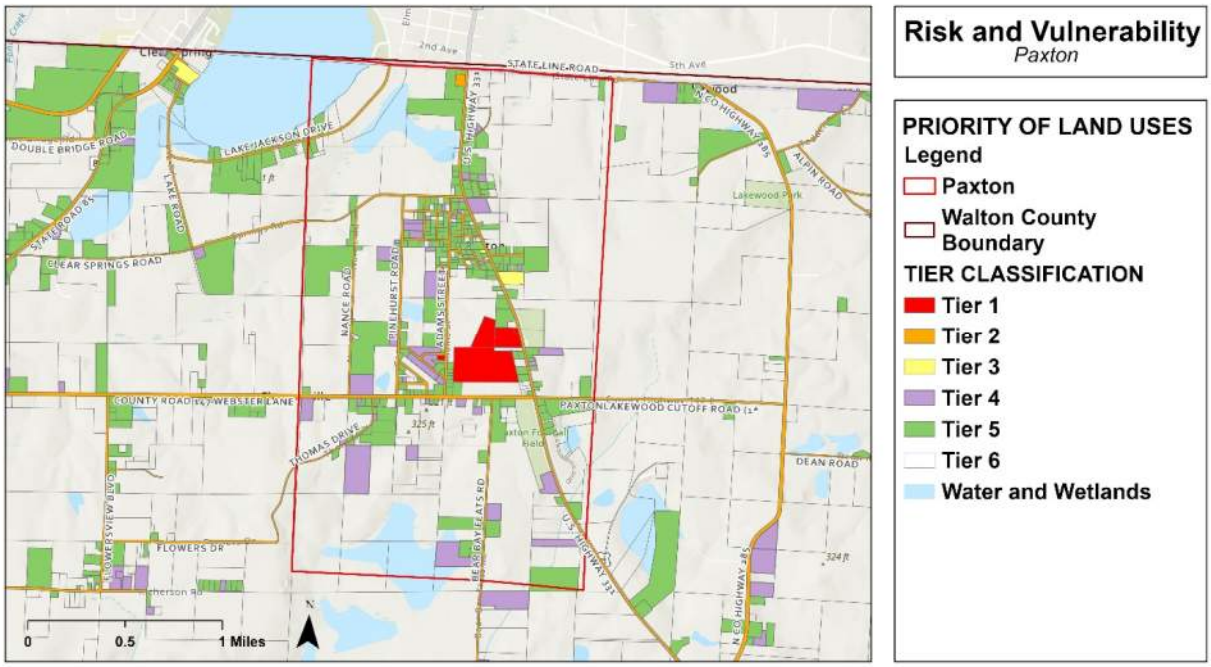

Figure 40. Critical Facilities (priority of land uses) map for Paxton. Processed by FAU.

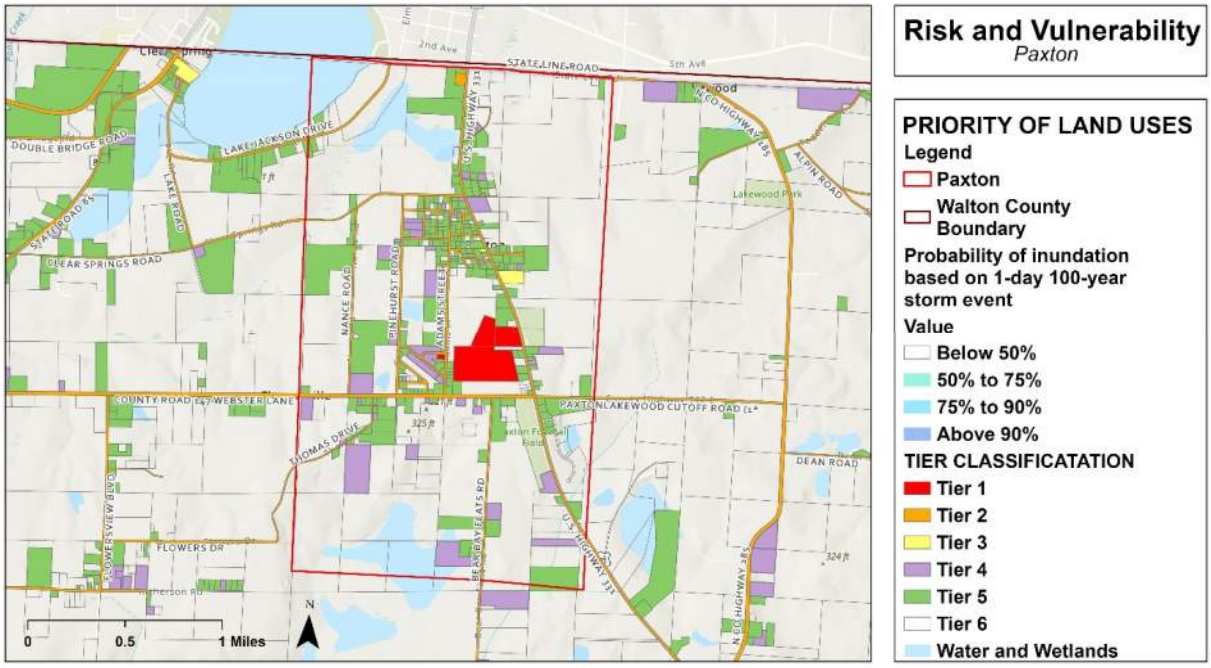

Figure 41. Critical Facilities (priority of land uses) map overlaid in the 1-day 100-years storm event for Paxton. Processed by FAU.

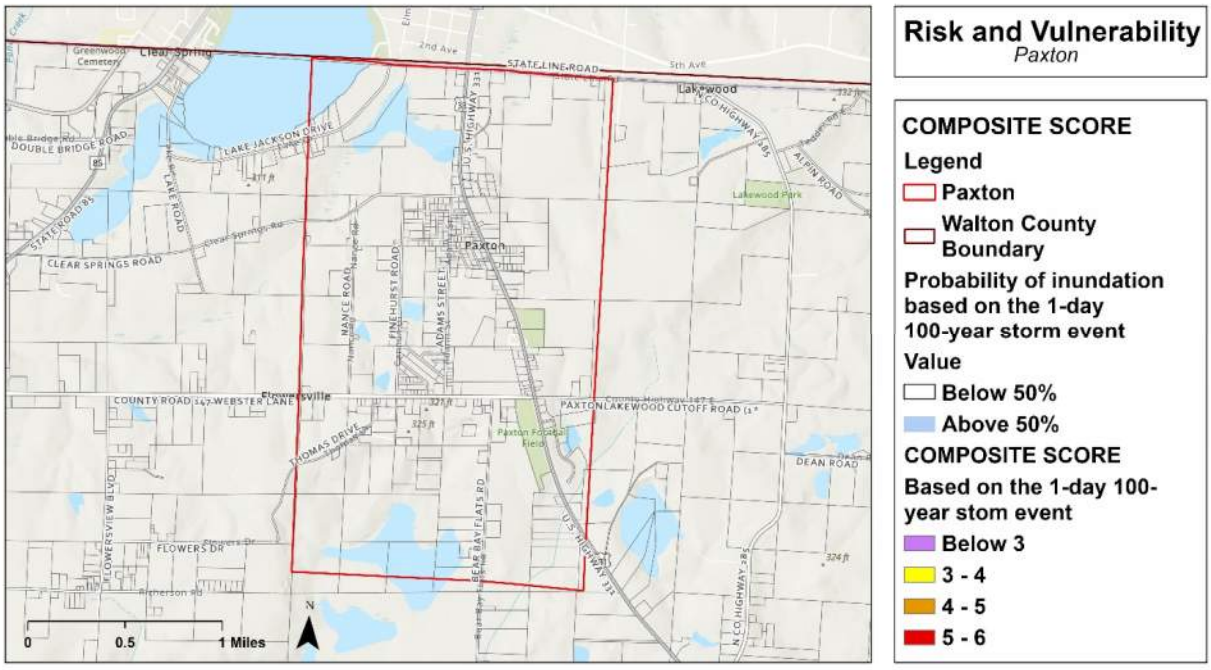

Figure 42. Composite Score map based on 1-day 100-years storm event, overlaid in flooding layer for Paxton. Processed by FAU.

2.4.3 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030601. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.4 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-years storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-years storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030601. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030601	24506.97
All of the 1-day 100-years storm event inundation	**7.81**
Subtract	
A. Bodies of Water in 1-day 100-years inundation > 10 acres	0.00
B. Federal Land in 1-day 100-years inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-years inundation > 10 acres	0
D. State Land in 1-day 100-years inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-years inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-years inundation minus (A+B+C) or	7.81
With NO State Lands: All of the 1-day 100-years inundation minus (A+B+C+D+E)	7.81

2.4.5 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. Figure 43 indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

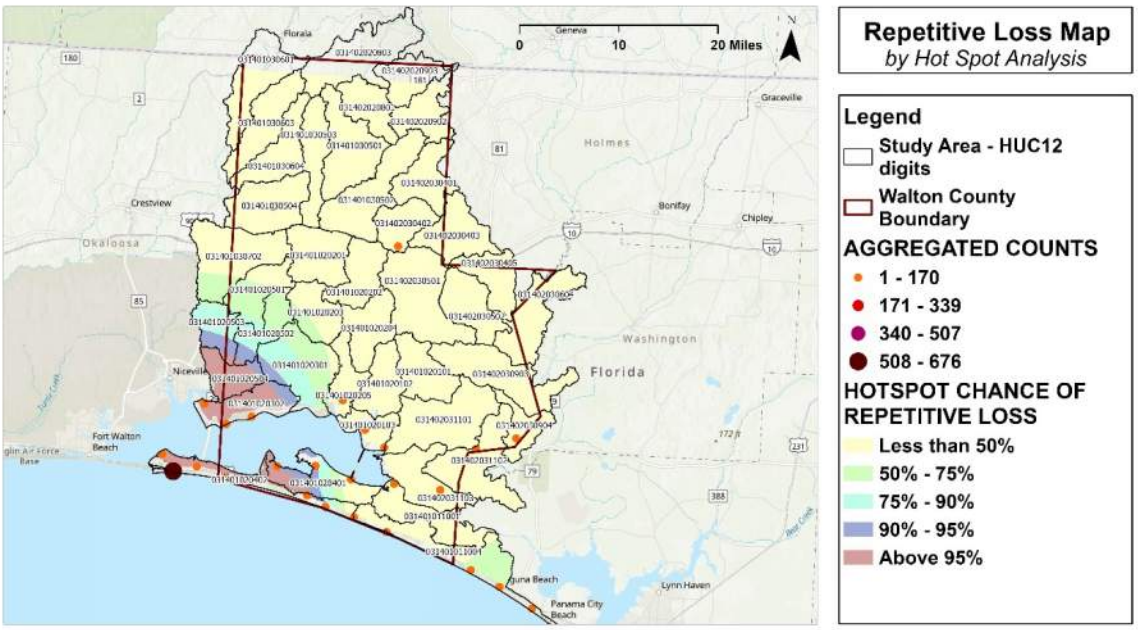

Figure 43. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.6 Priority Projects

Although there are a few parcels falling within classification tier 1, and a good amount of parcels falling within tiers 2 (roads), 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding is basically inexistent in the basin. Consequently, when considering the composite score, it is notable that the results are null, indicating no priority for intervention.

It is also important to mention that a good portion of the basin has not been included in the priority land use analysis and, consequently, in the composite score calculation. This omission is due to the project's reliance on land use data solely from Florida, and the basin has a portion on Alabama as well. The categories of land use maps in Alabama would be different, making it impossible to match the data from two different databases in different states. As a result, there is a slight possibility that there may be priority projects on the Alabama side of the basin of which we are not aware.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030603) is highlighted among all the HUCs to help identifying its location. (Figure 3).

A small town, Paxton, shares a portion of its boundary with the basin. Demographic data and other characteristics of Paxton, along with other cities in Walton County, will be discussed later.

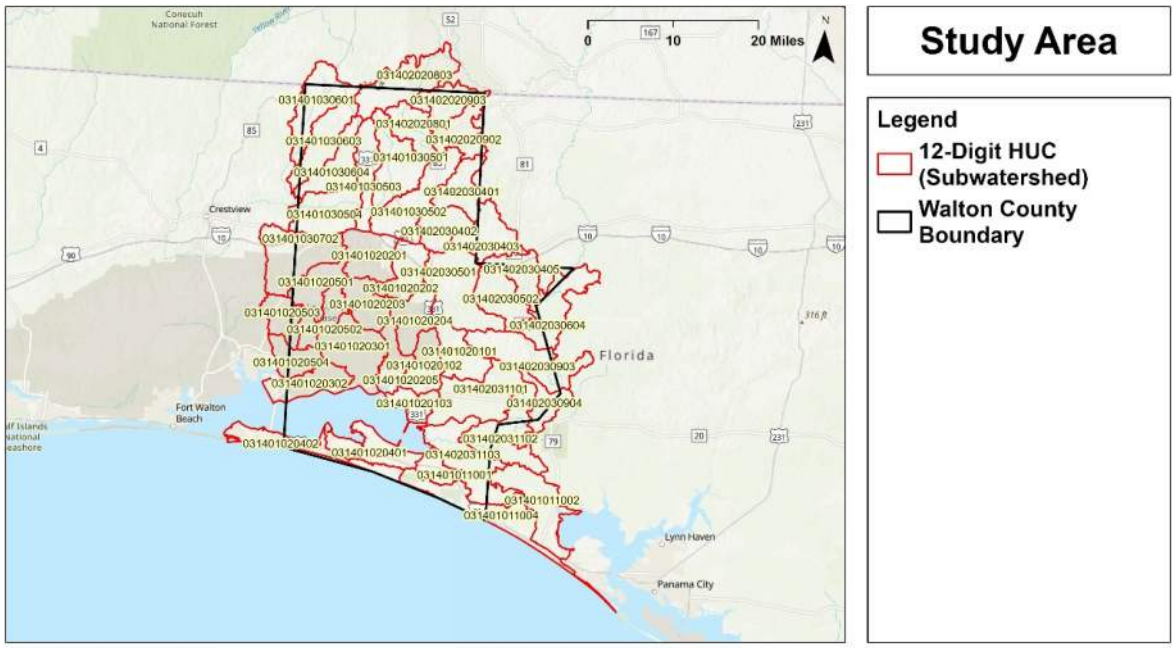

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

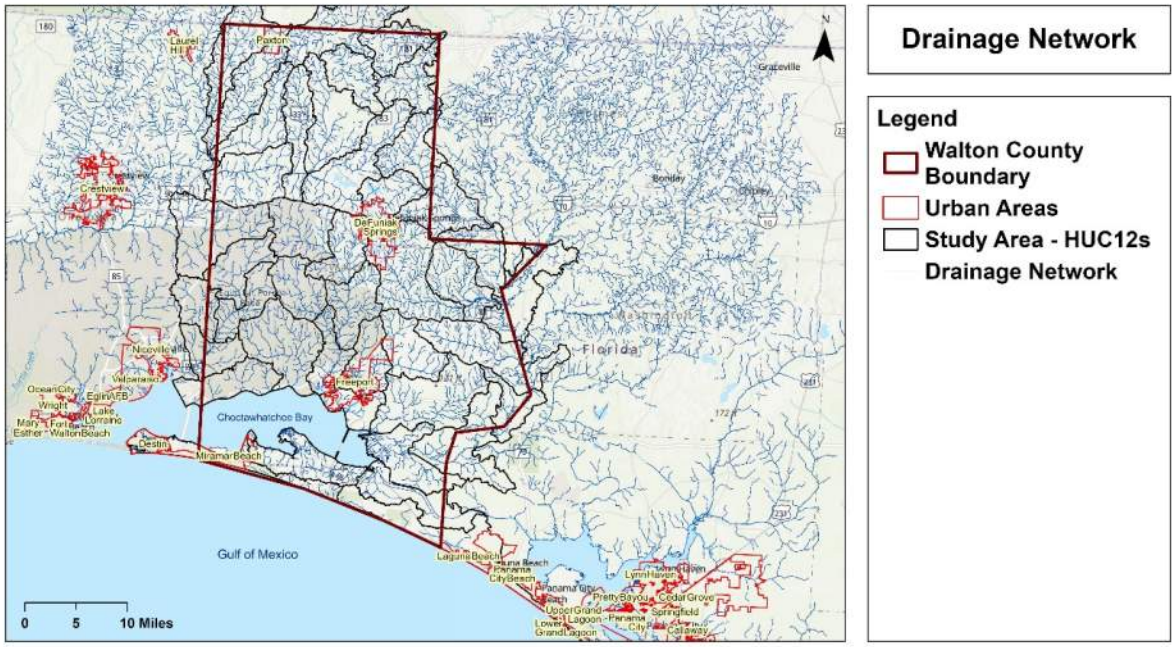

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

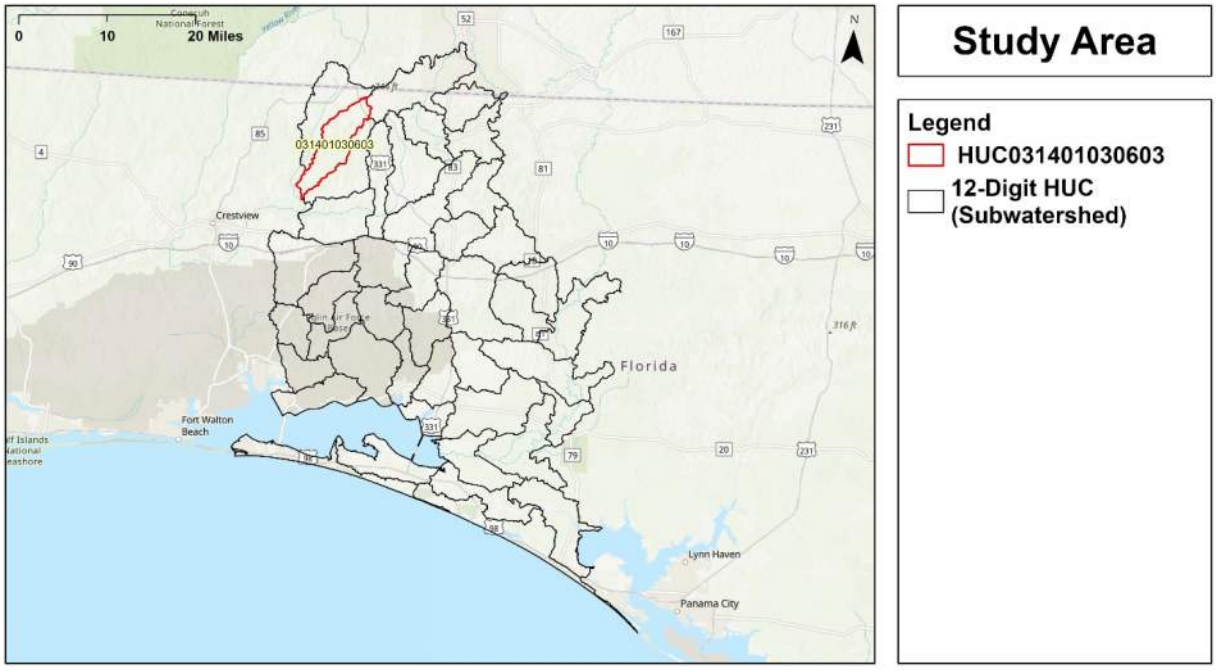

Figure 3. HUC 031401030603 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

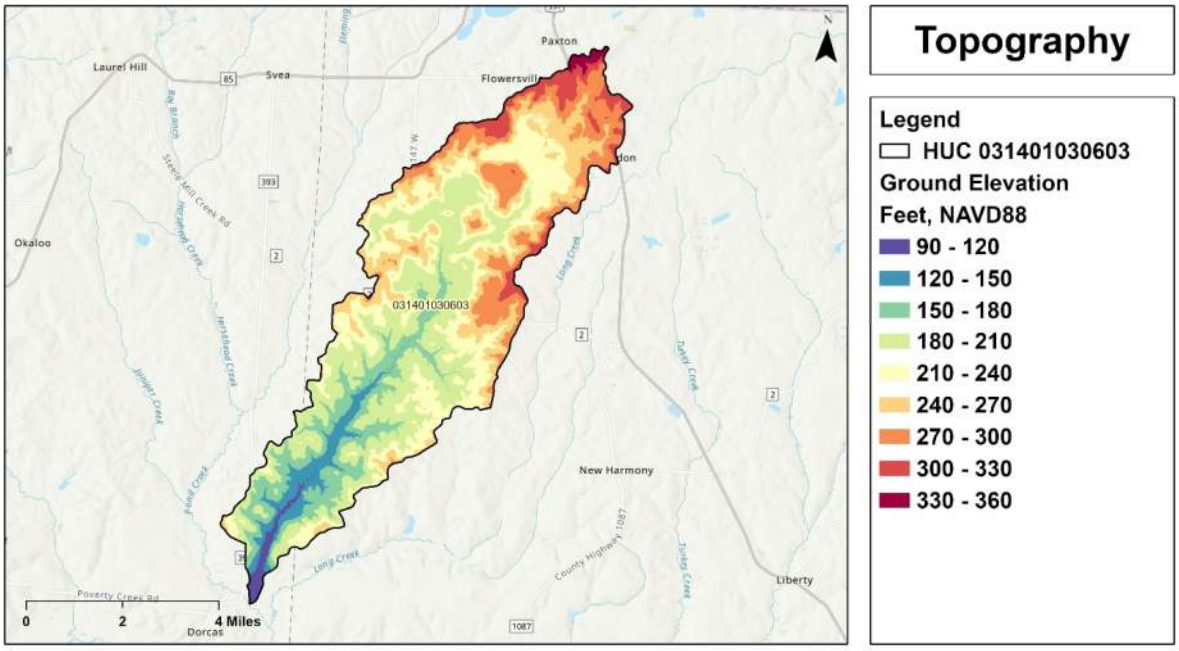

Figure 4. Topographic map of the HUC 031401030603 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030603 sub-watershed is shown in **Error! Reference source not found.**.

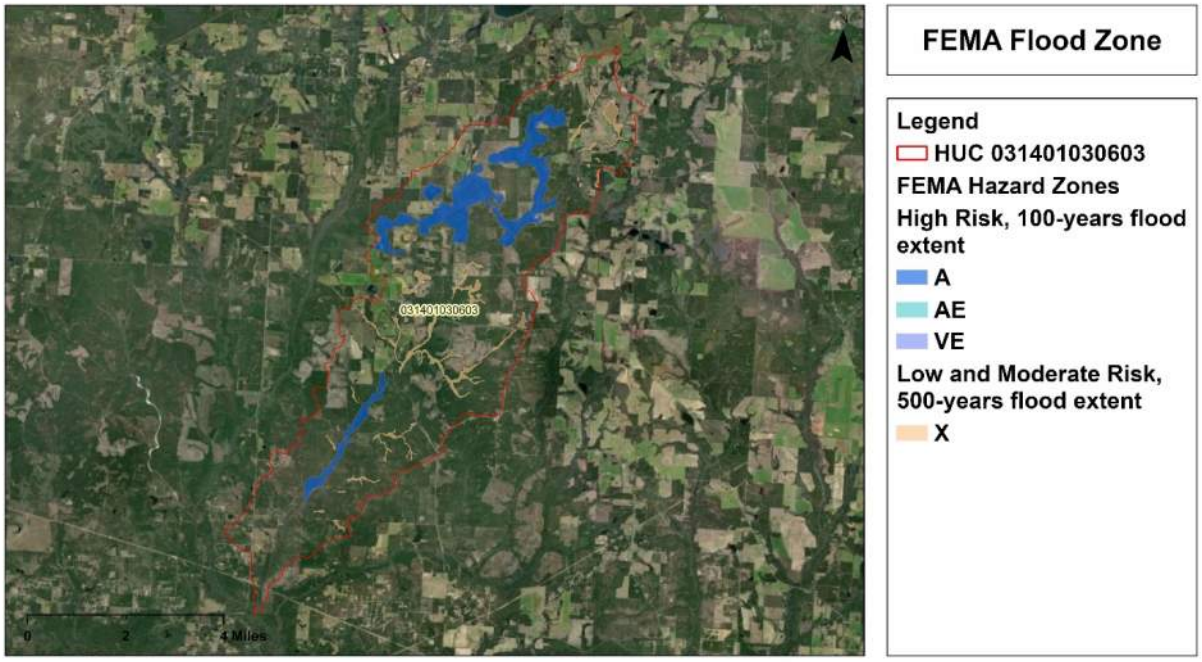

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030603 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination

between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030603 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

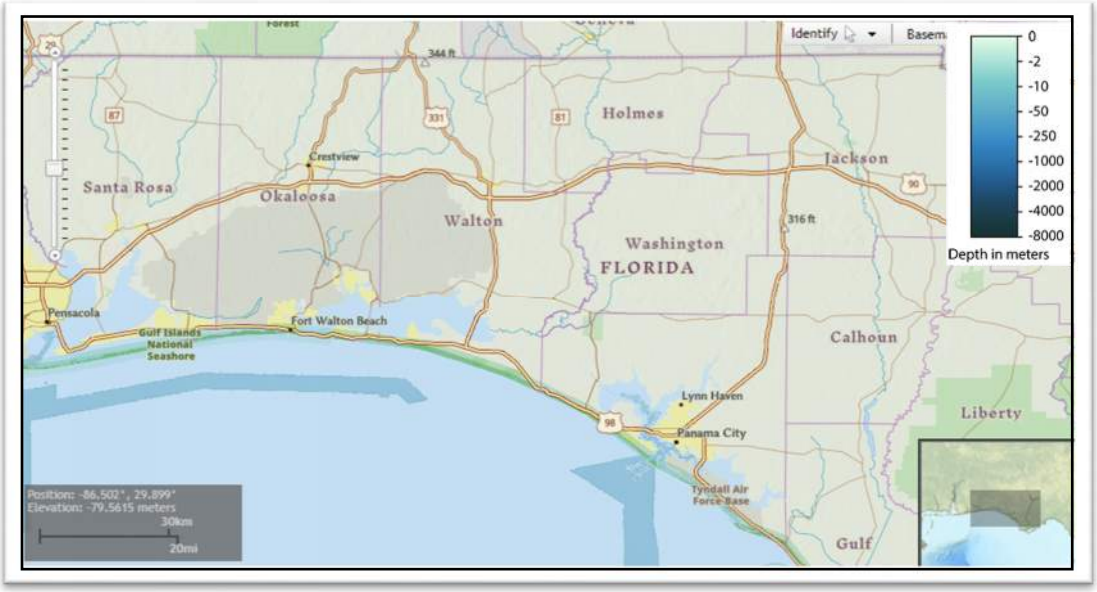

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

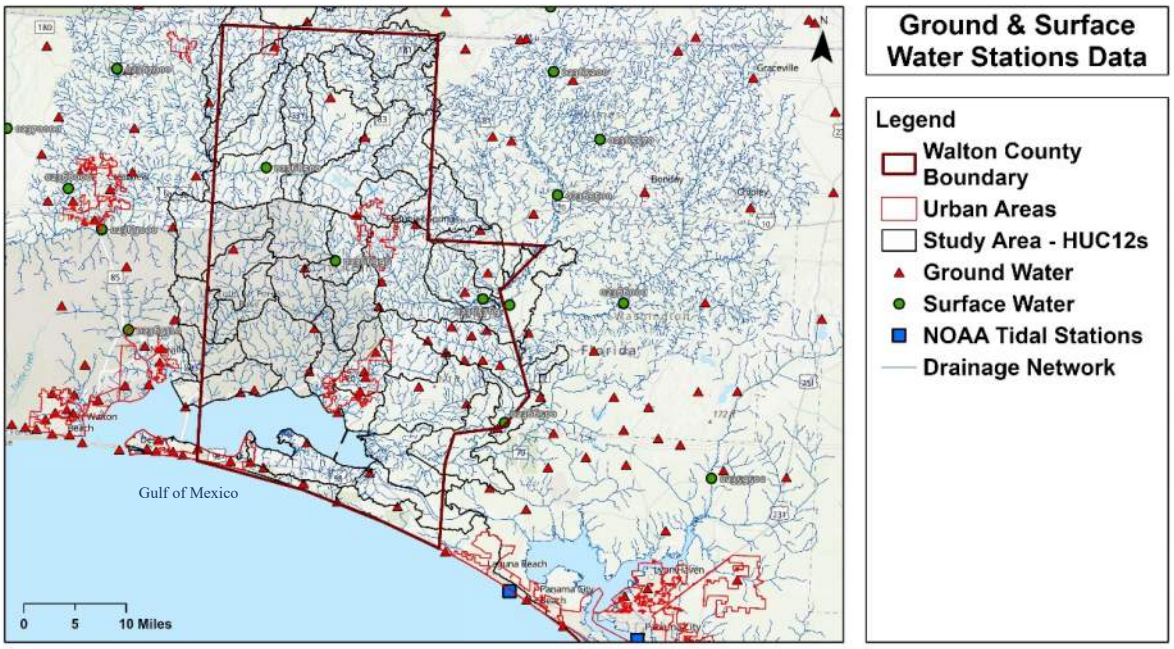

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030603 has no major rivers and canals, but creeks, include:

- Pine Log Creek
- East Branch Pine Log Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030603, which is USGS 02368500 Shoal River.

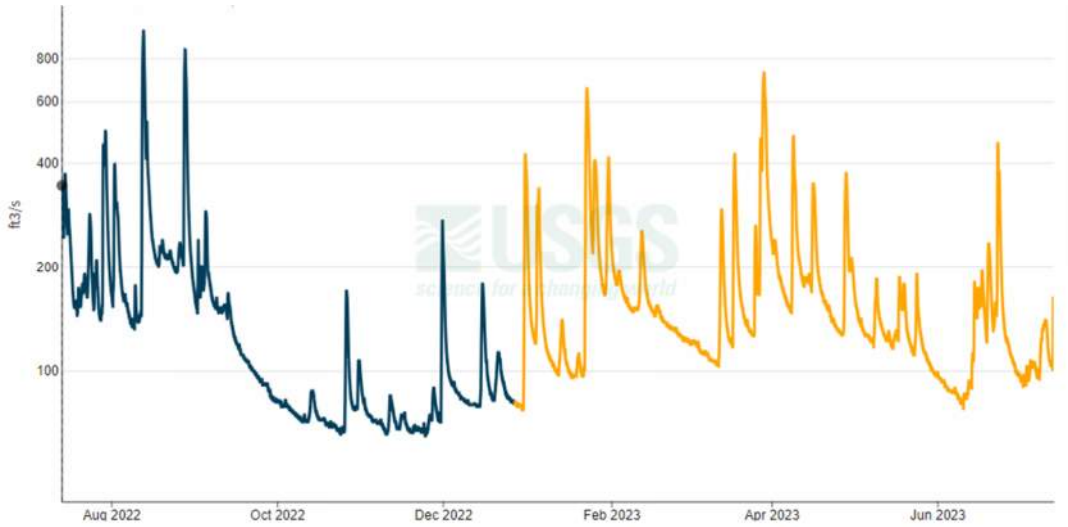

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030603 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401030603 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

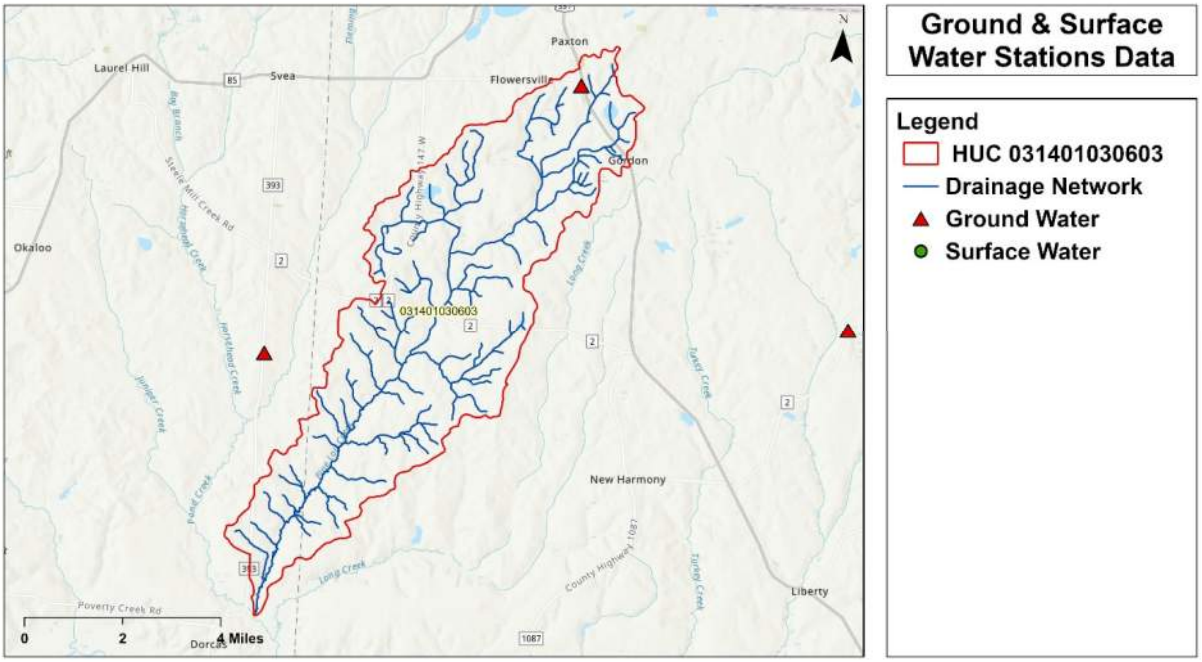

Figure 9. Ground and Surface Water Stations in the HUC 031401030603 sub-watershed, processed by FAU.

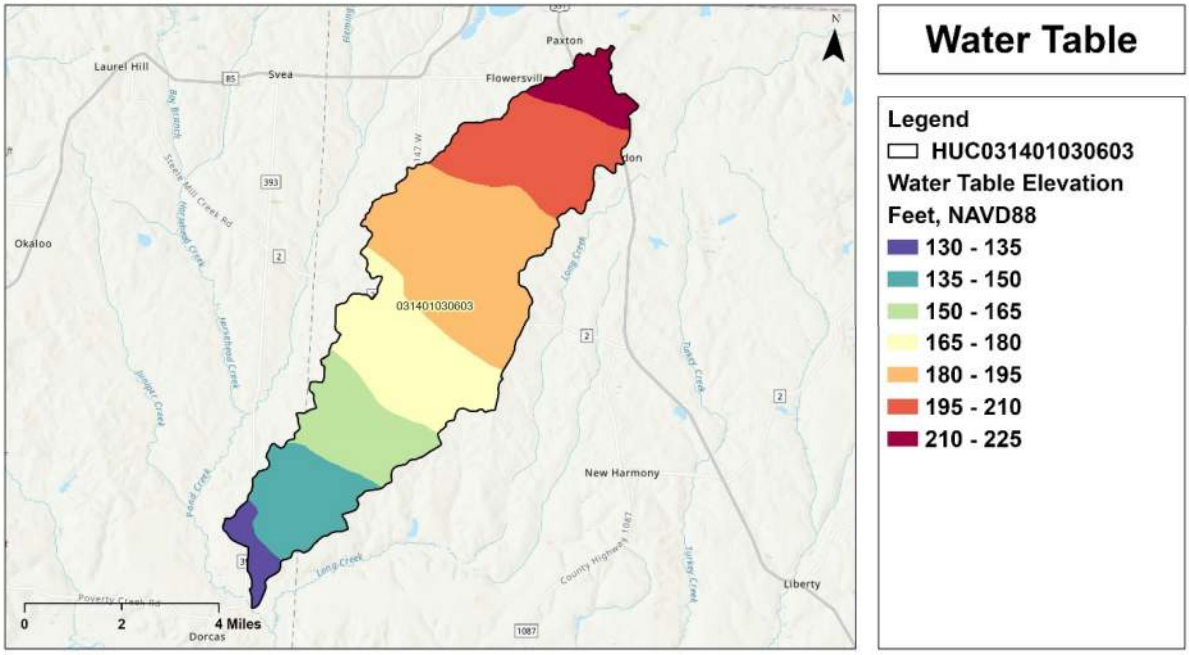

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030603 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

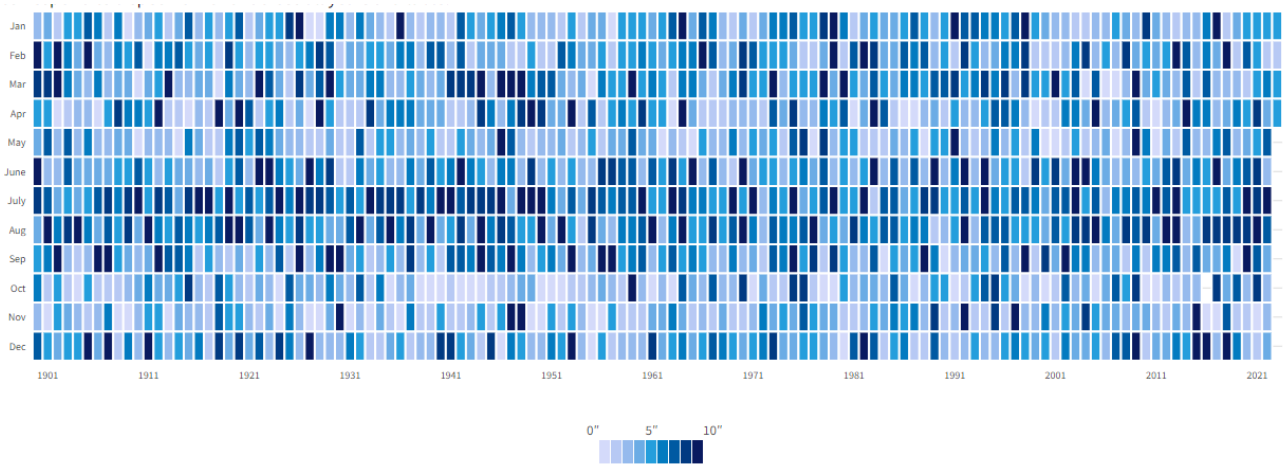

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

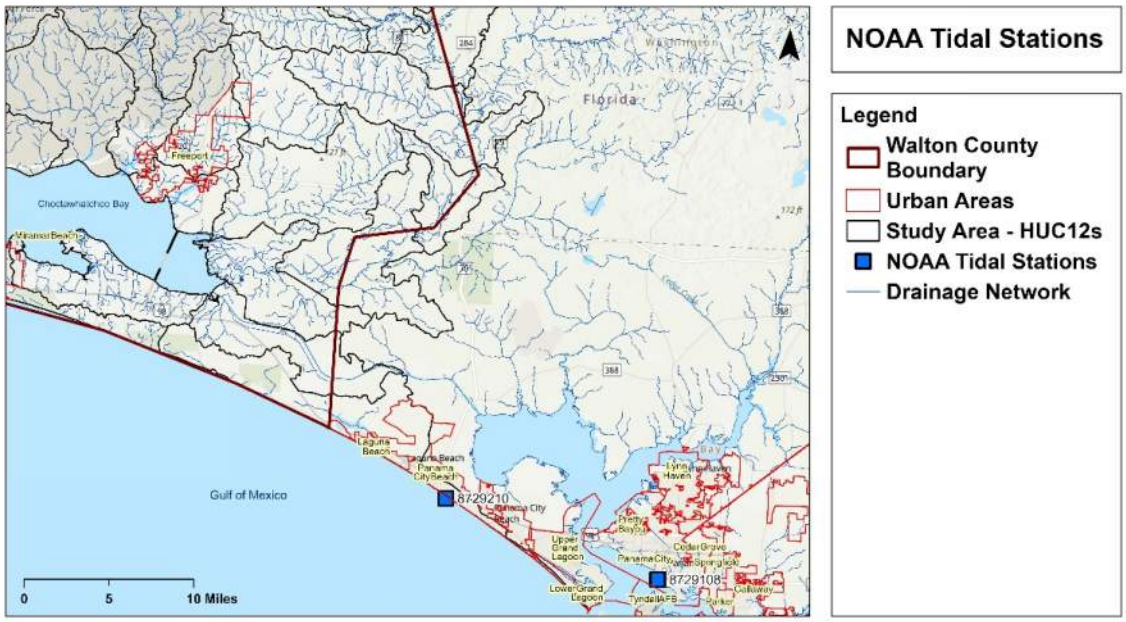

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

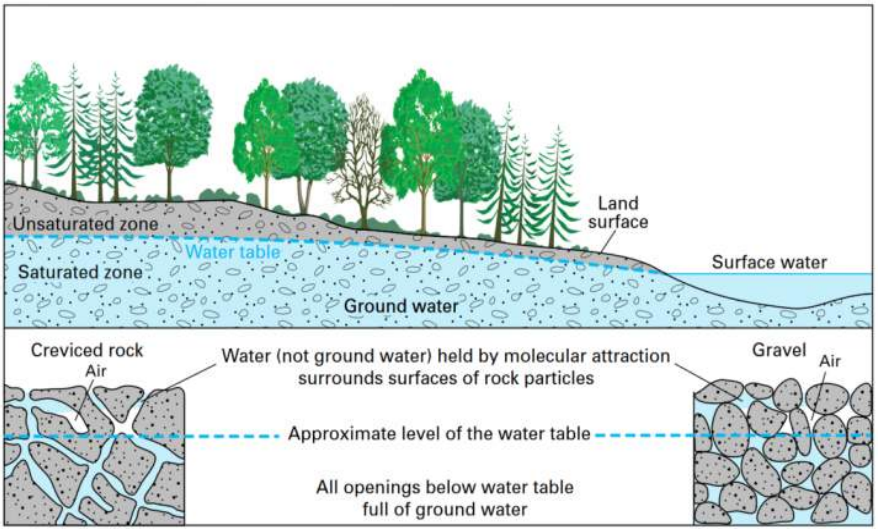

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

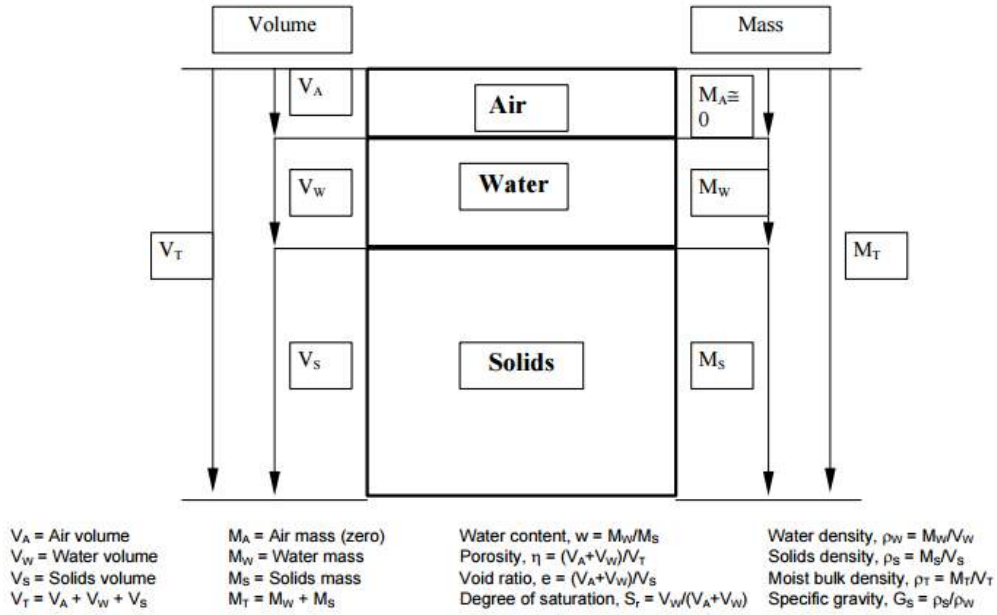

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

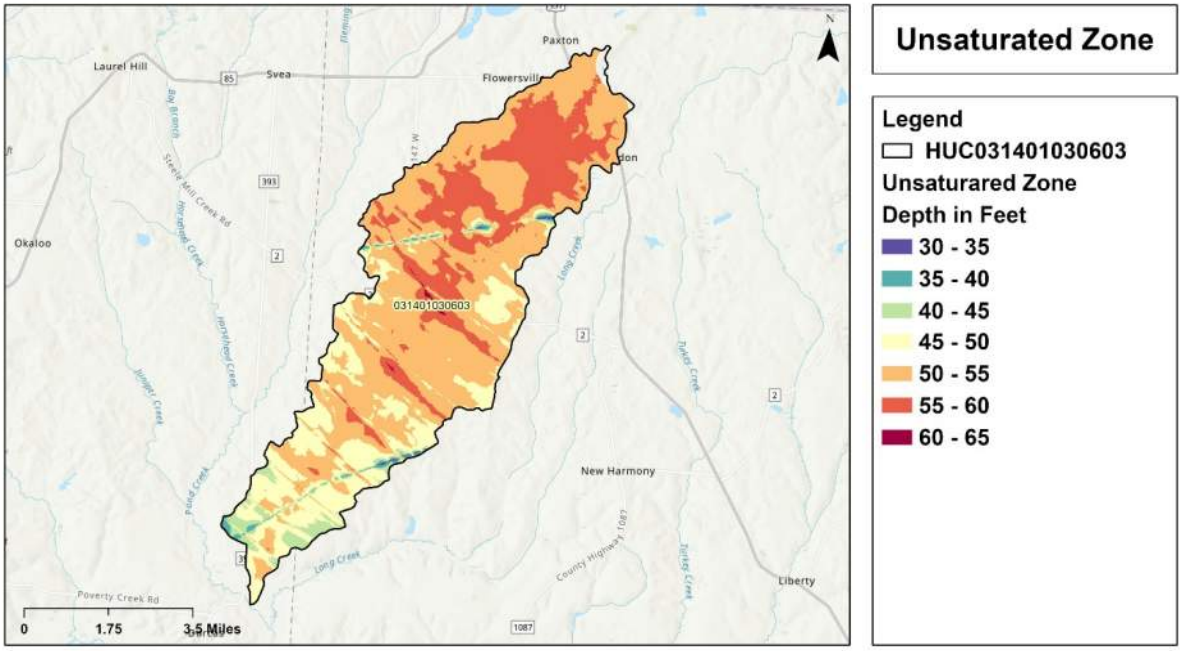

Figure 15. Unsaturated zone map for HUC 031401030603, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A great portion of the basin has enough soil storage capacity, ranging between 45 to 60 inches of capacity left.

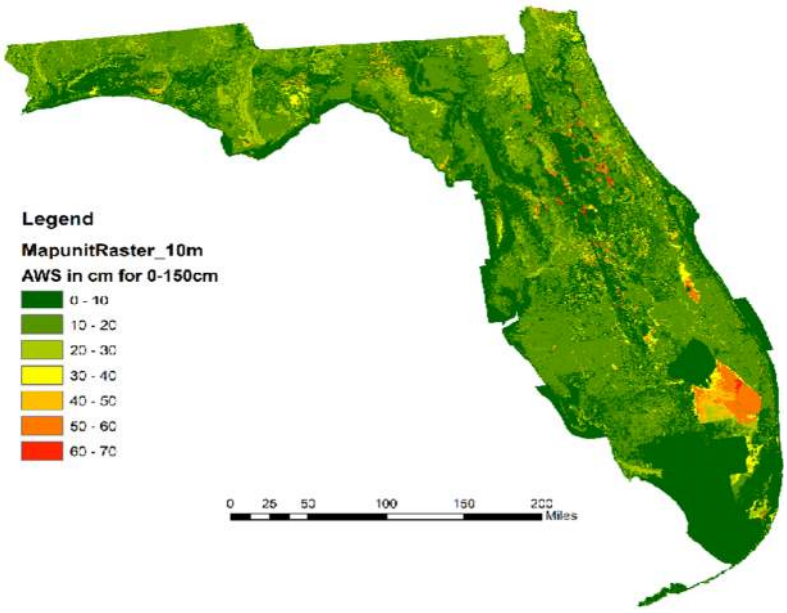

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

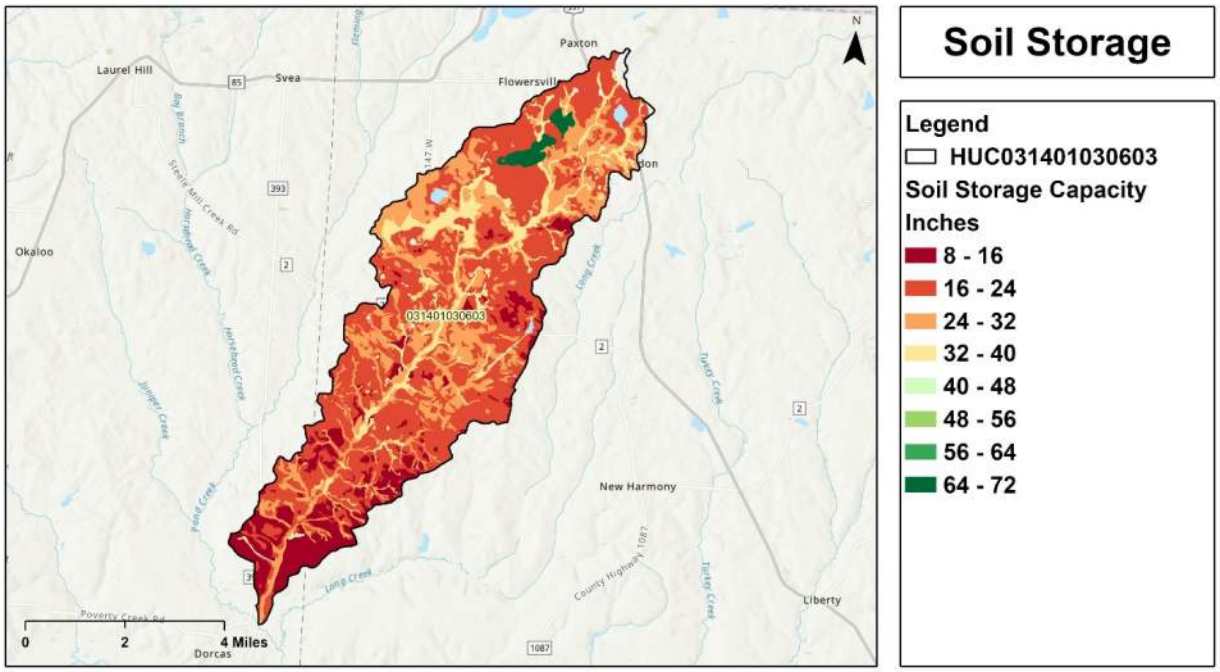

Figure 17. Water storage capacity of soil for the HUC 031401030603 (inches), processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

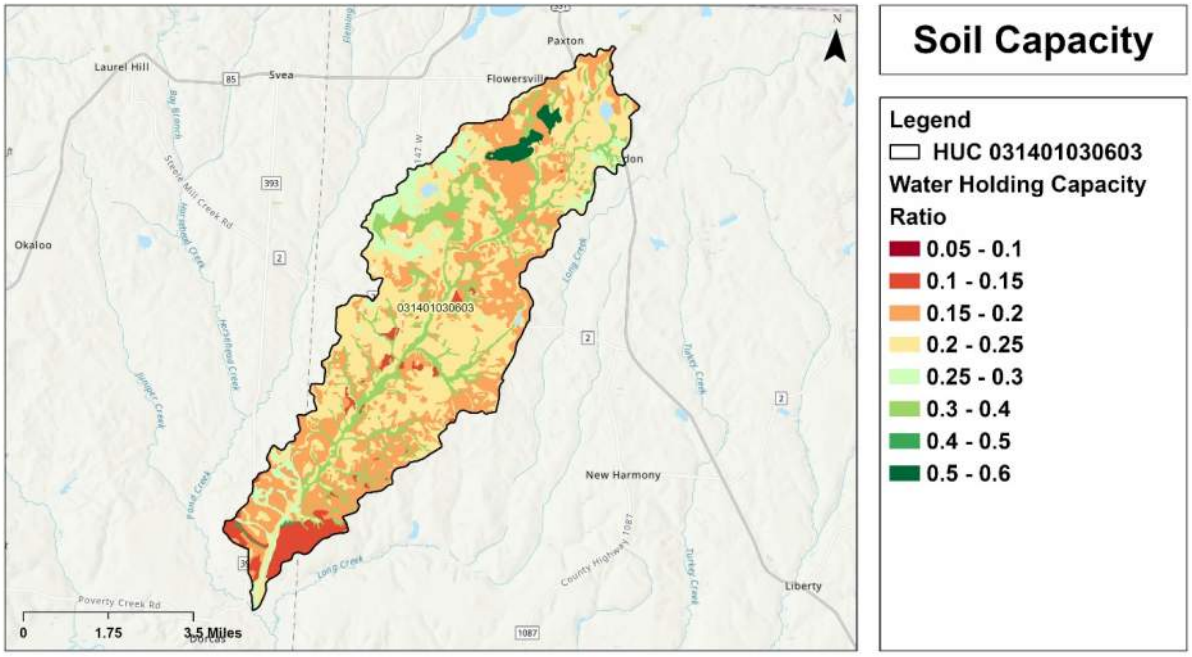

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030603, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

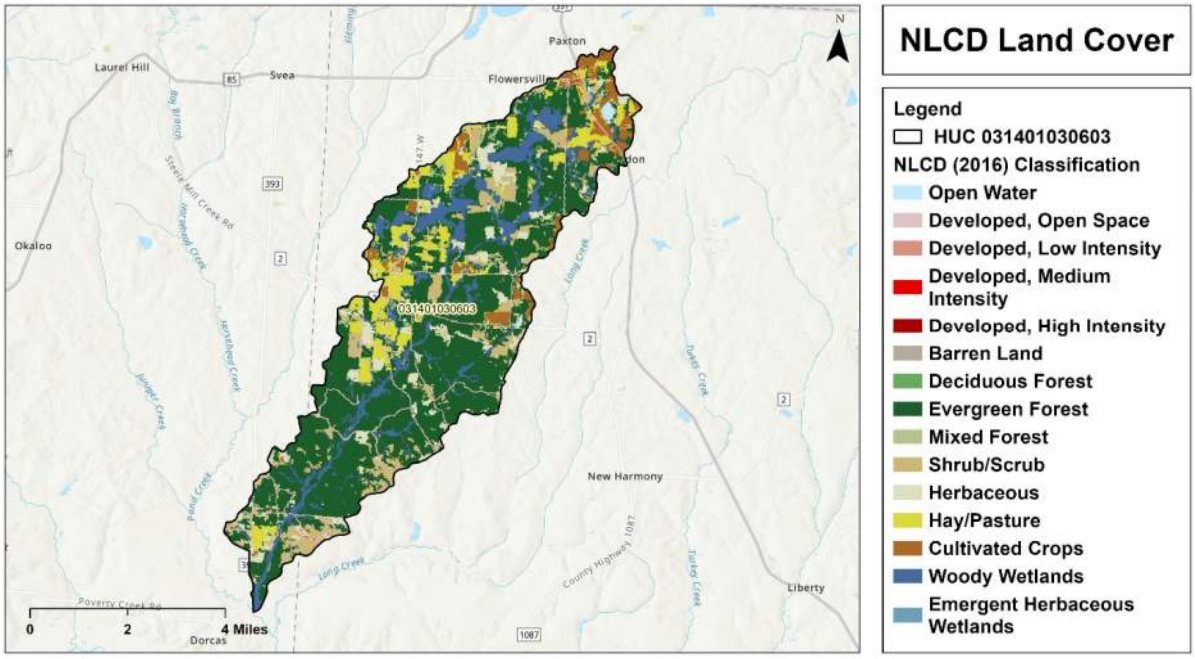

Figure 19. Land use in the HUC 031401030603 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

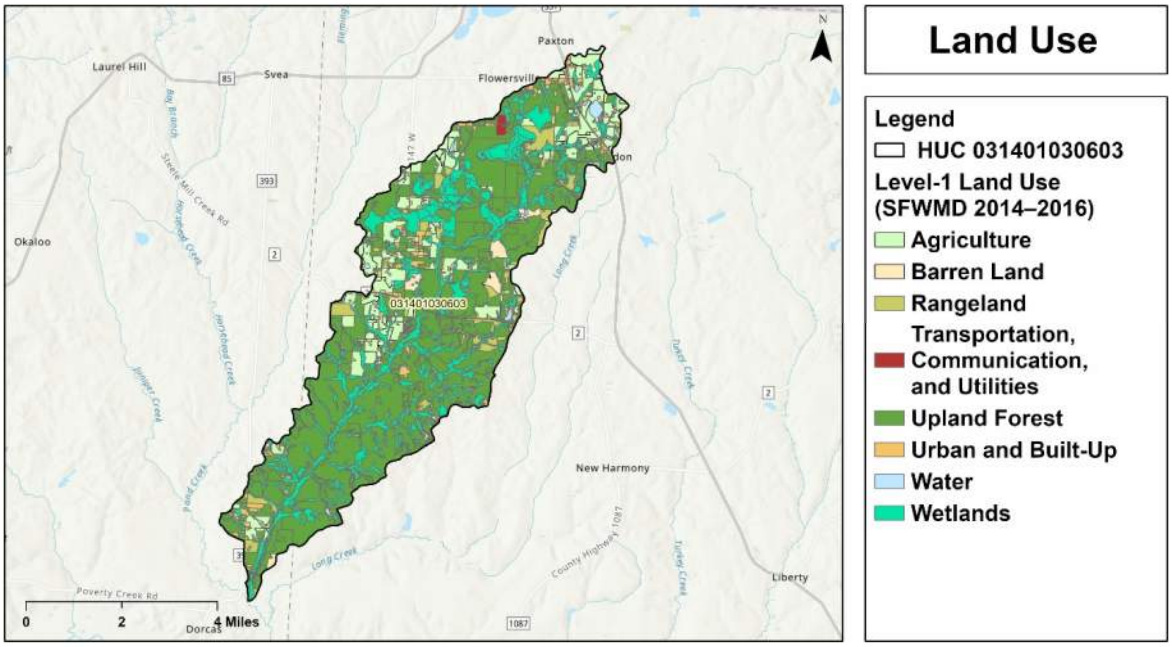

Figure 20. Land use in the HUC 031401030603 (2023 Florida Geographic Data Library (FGDL))), processed by FAU.

In the HUC 031401030603 sub-watershed, mostly of the area is upland forest, with 57.91%. The second place is wetlands, with 16.82%, followed by agriculture, with 13.92%. There is no much developed land in the HUC – only 2.86% is urban and built-up and only 1.08% is Transportation, Communication, and Utilities, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030603 subwatershed (2023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	3752.82	13.92%
Barren Land	355.57	1.32%
Rangeland	1115.40	4.14%
Transportation, Communication, and Utilities	291.86	1.08%
Upland Forest	15615.50	57.91%
Urban and Built-Up	771.94	2.86%
Water	524.25	1.94%
Wetlands	4536.08	16.82%
Grand Total:	**26963.42**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

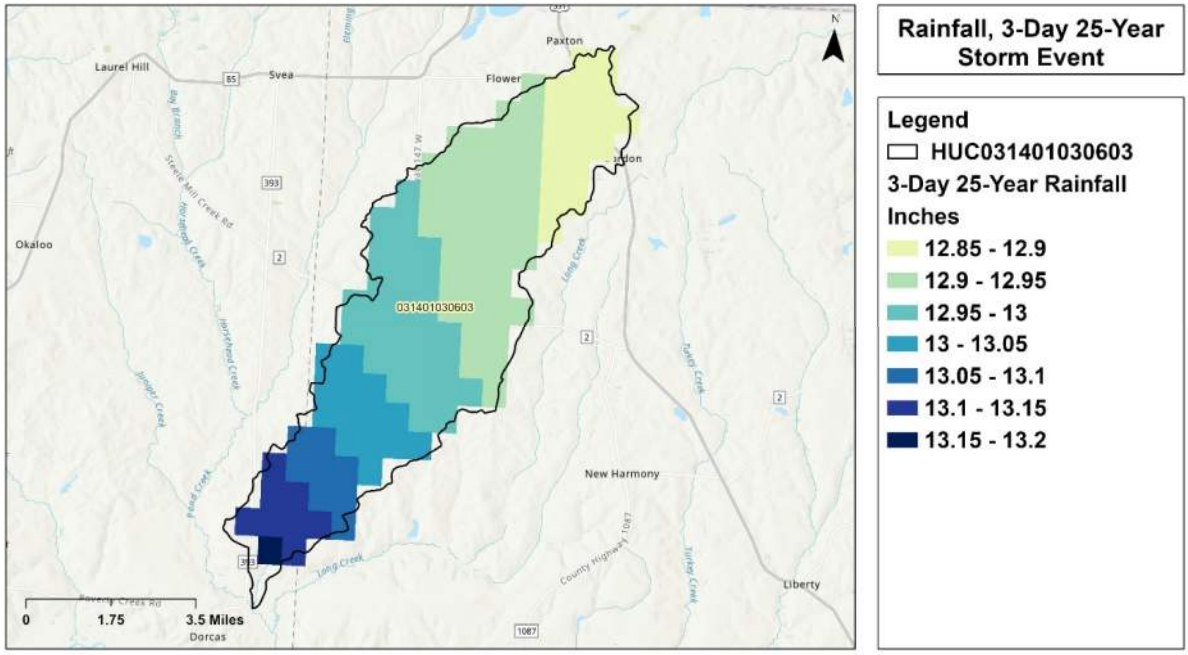

Figure 21. Rainfall distribution map across HUC 031401030603 sub-watershed, for 3-day 25-year storm event, processed by FAU.

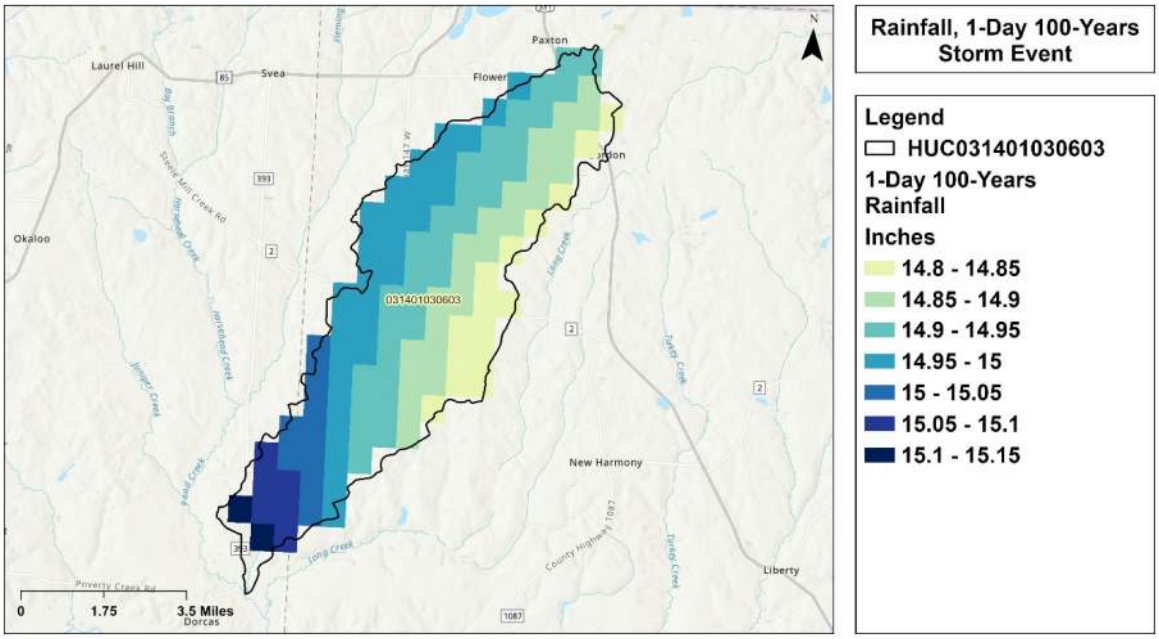

Figure 22. Rainfall distribution map across HUC 031401030603 sub-watershed, for 1-day 100-year storm event, processed by FAU.

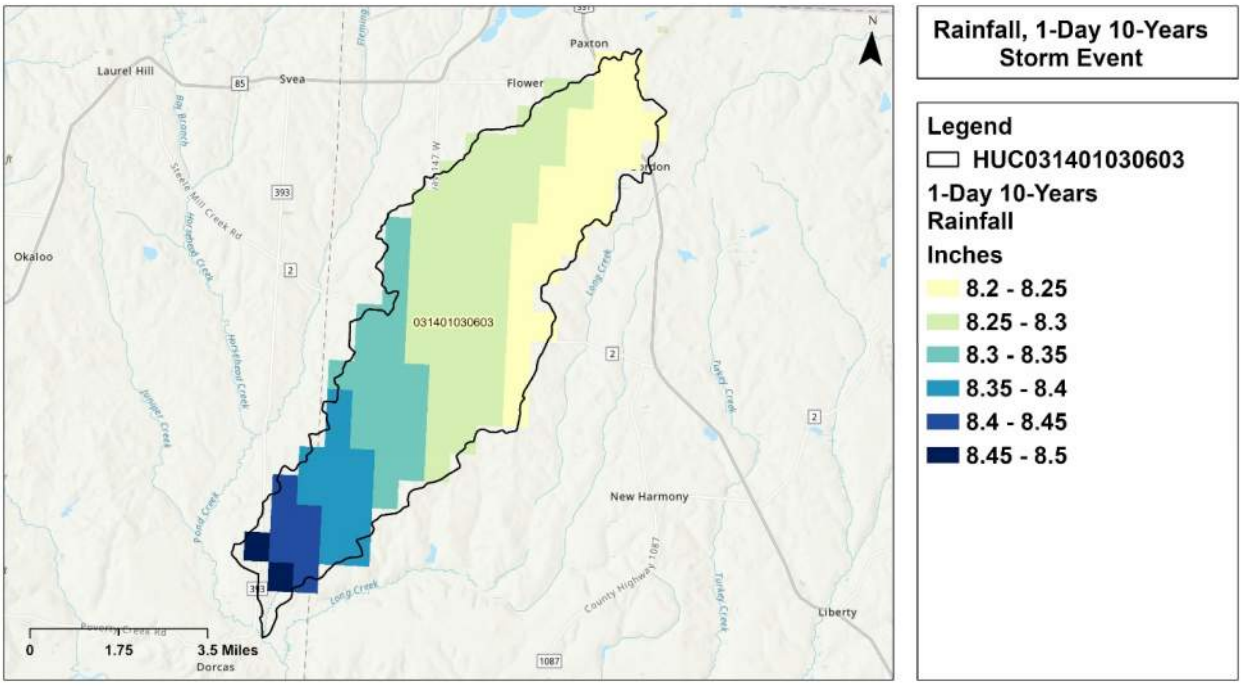

Figure 23. Rainfall distribution map across HUC 031401030603 sub-watershed, for 1-day 10-year storm event, processed by FAU.

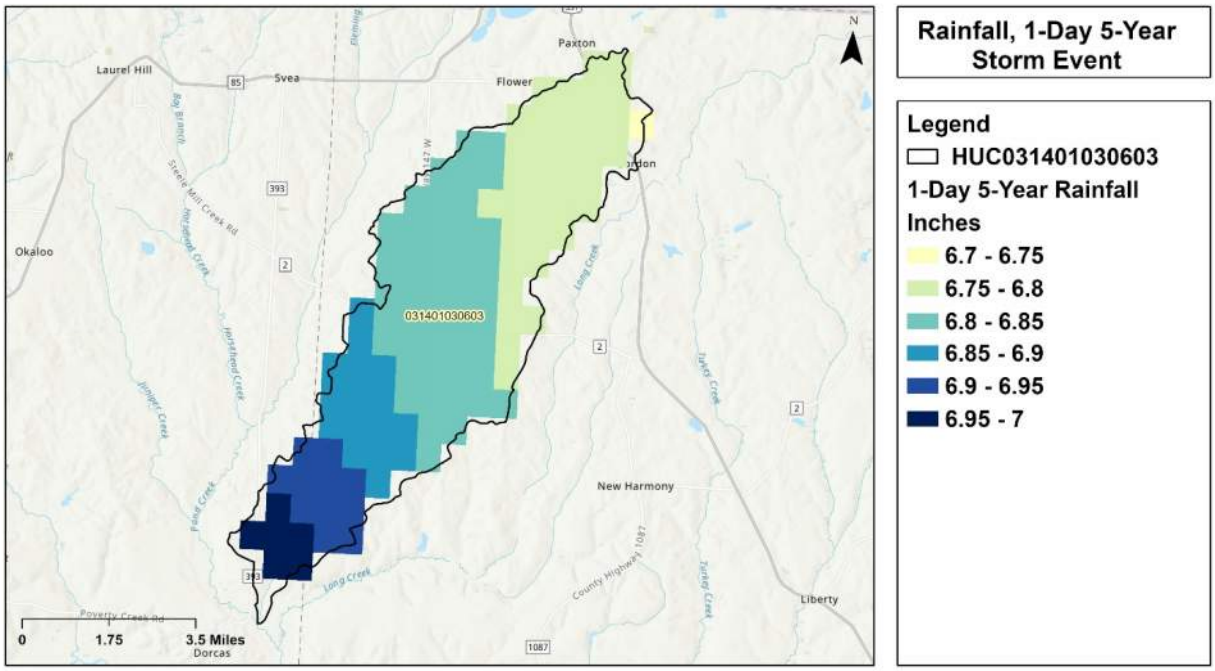

Figure 24. Rainfall distribution map across HUC 031401030603 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically

aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

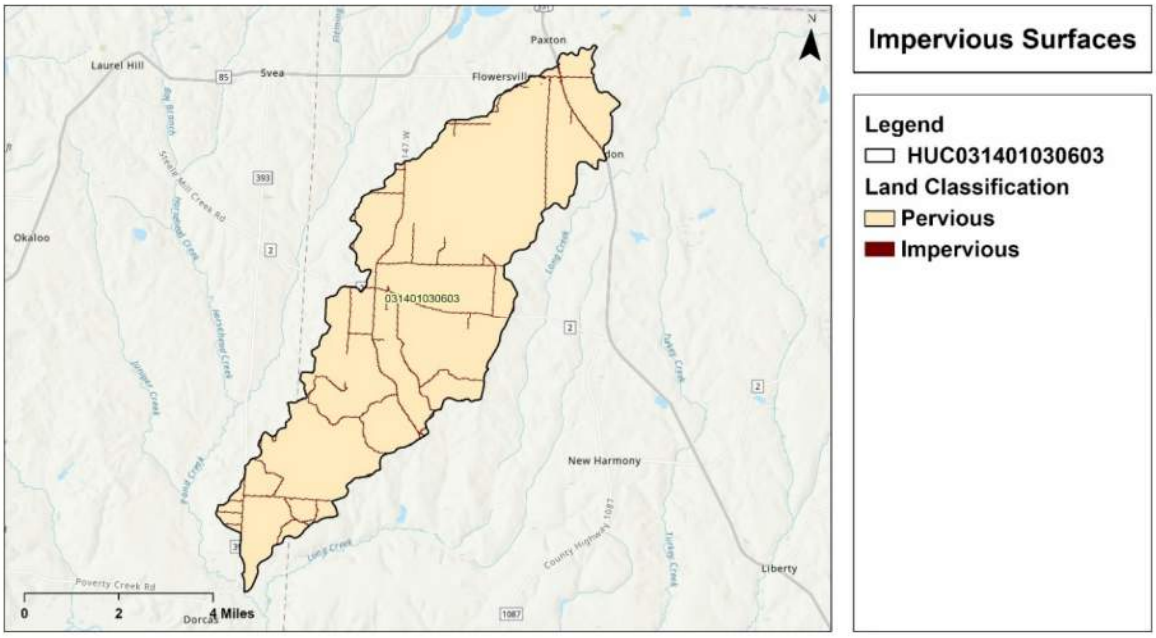

Figure 25. Impervious area map for the HUC 031401030603 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

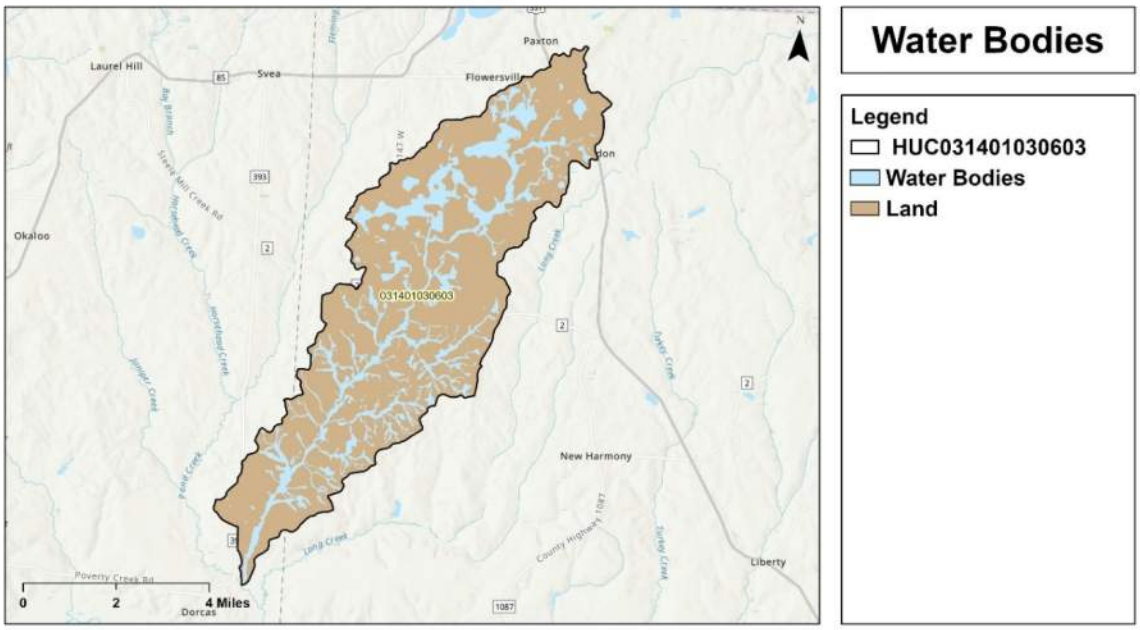

Figure 26. Water bodies map for the HUC 031401030603 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract

level. Based on the census data for the study area, Table 5 outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, , such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

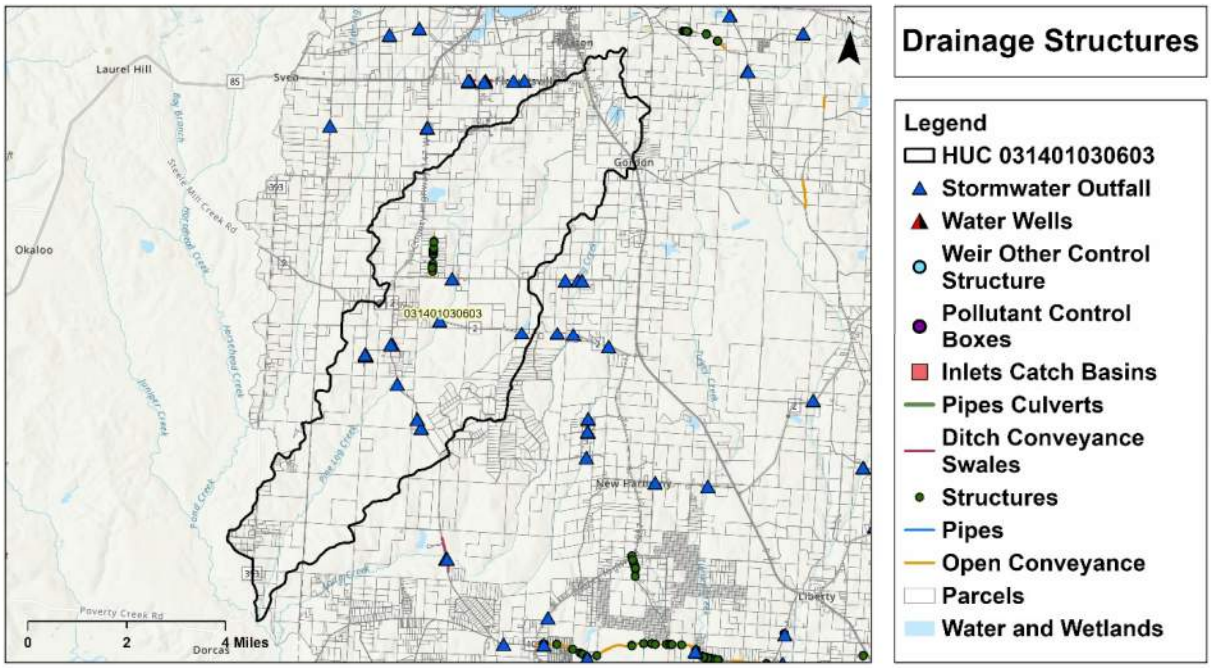

Figure 27. Stormwater Infrastructure for the HUC 031401030603. Processed by FAU.

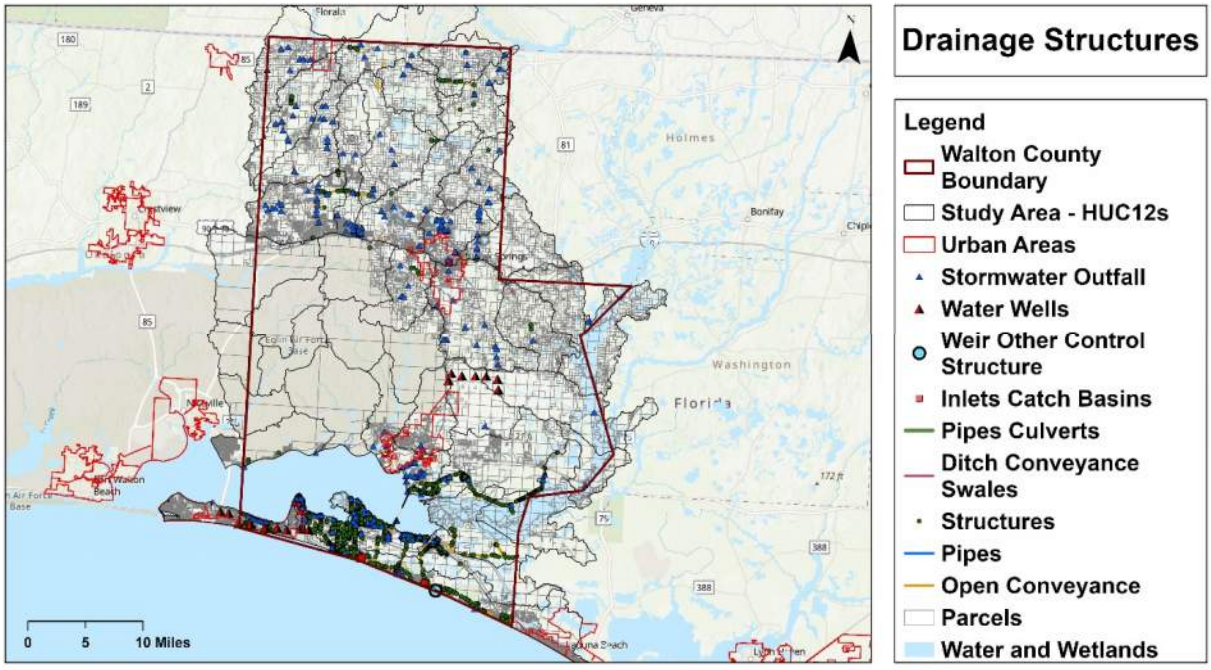

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030603 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

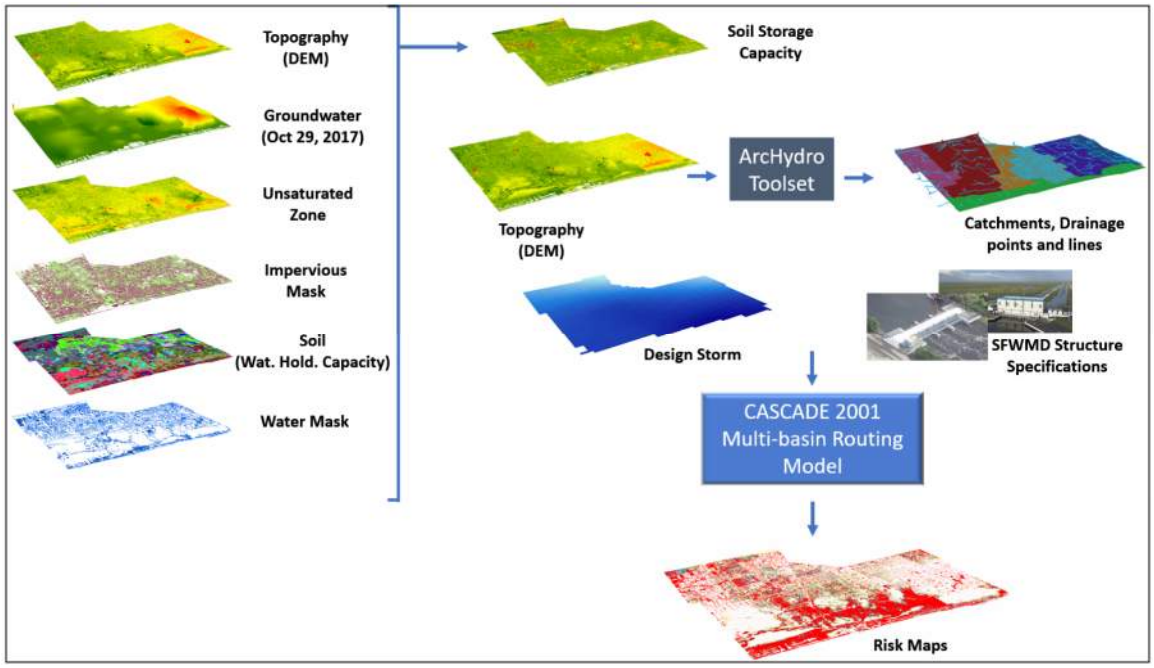

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

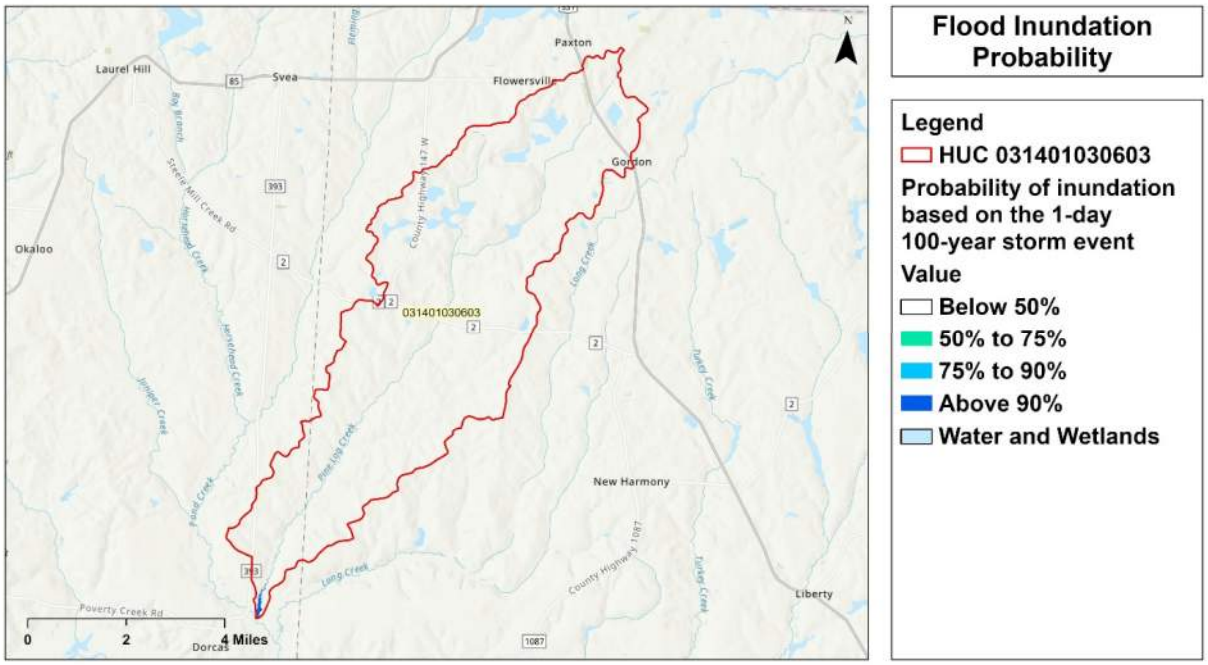

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030603, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation

and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations,

Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding, almost imperceptible is noted at the entrance to the creek into the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, sea level rise should not impact the HUC, therefore SLR scenarios were not calculated.

The design storm simulation determined that approximately 0.1% of the HUC total area or only 0.033 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.12% of the HUC's total area, or 0.038 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.09% of the HUC's total area, or 0.029 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.09% of the HUC's total area, or 0.029 mi^2, would be expected to be inundated

during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030603 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	32.791	0.033	99.90%	0.10%
1-day 100-year	32.786	0.038	99.88%	0.12%
1-day 10-year	32.795	0.029	99.91%	0.09%
1-day 5-year	32.795	0.029	99.91%	0.09%

Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations.
Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have

lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is

converted to a 6-point scale termed as the Flood Risk Factor, as shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.**depict the HUC 031401030603 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

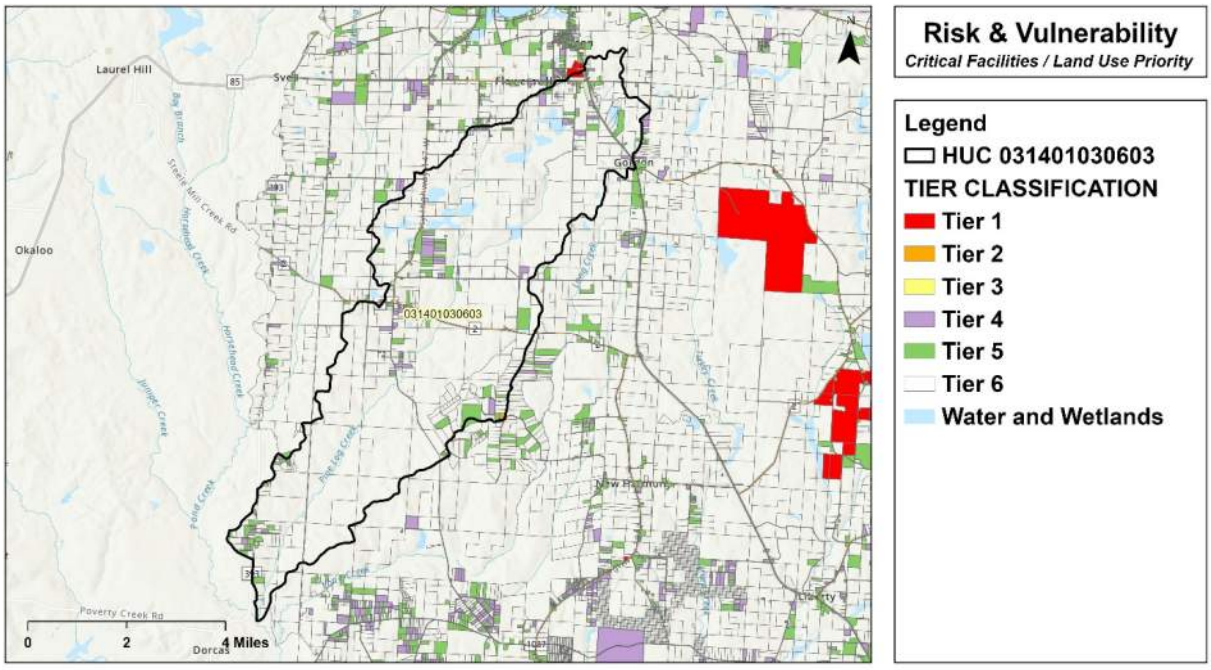

Figure 35. HUC 031401030603 sub-watershed Critical Facilities (priority of land uses) map. Processed by FAU.

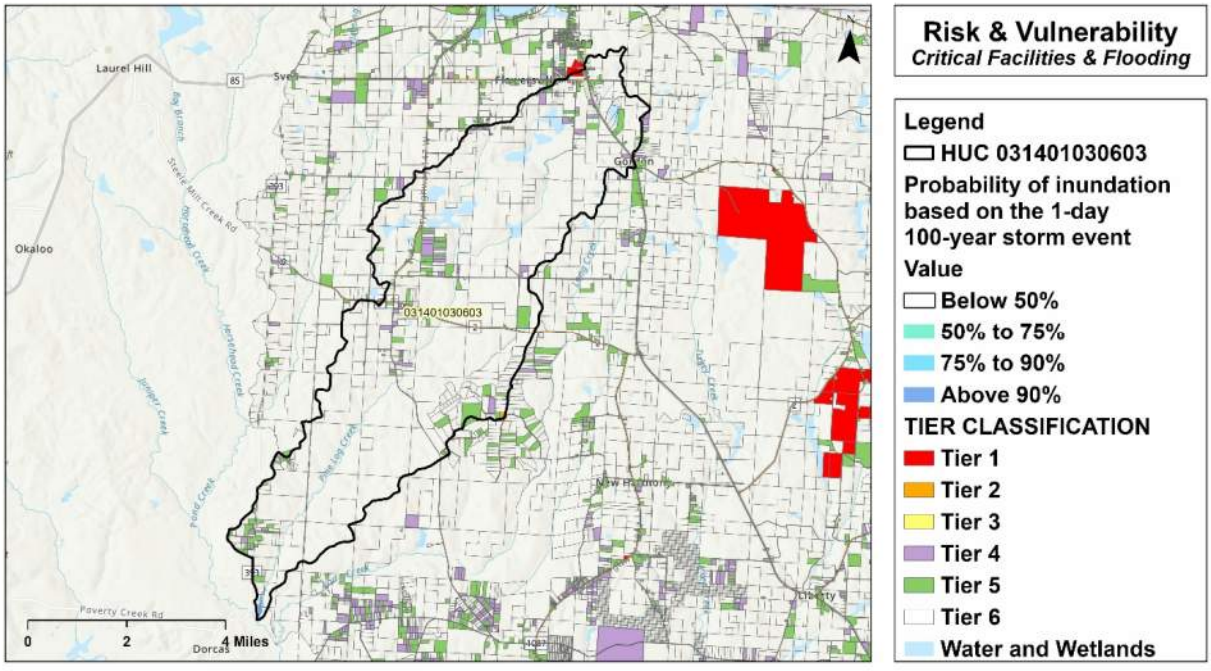

Figure 36. HUC 031401030603 sub-watershed Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

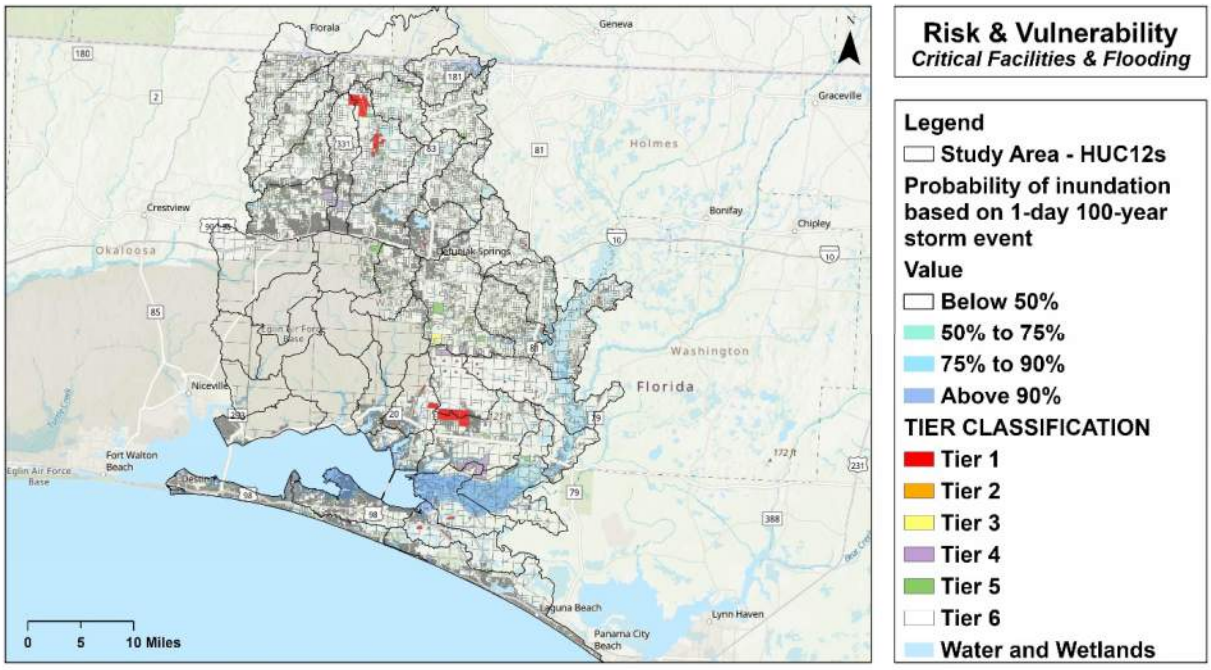

Figure 37. Walton County (mosaic) - Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation for Walton County. Processed by FAU.

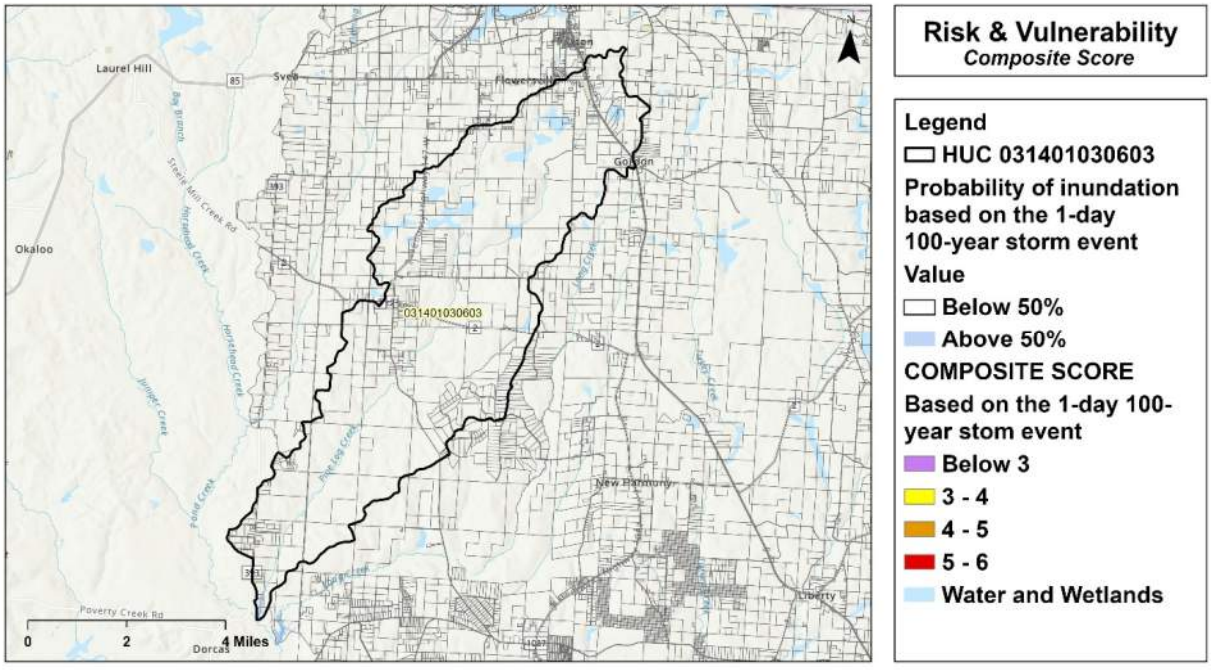

Figure 38. Walton County (mosaic) - Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation for Walton County. Processed by FAU.

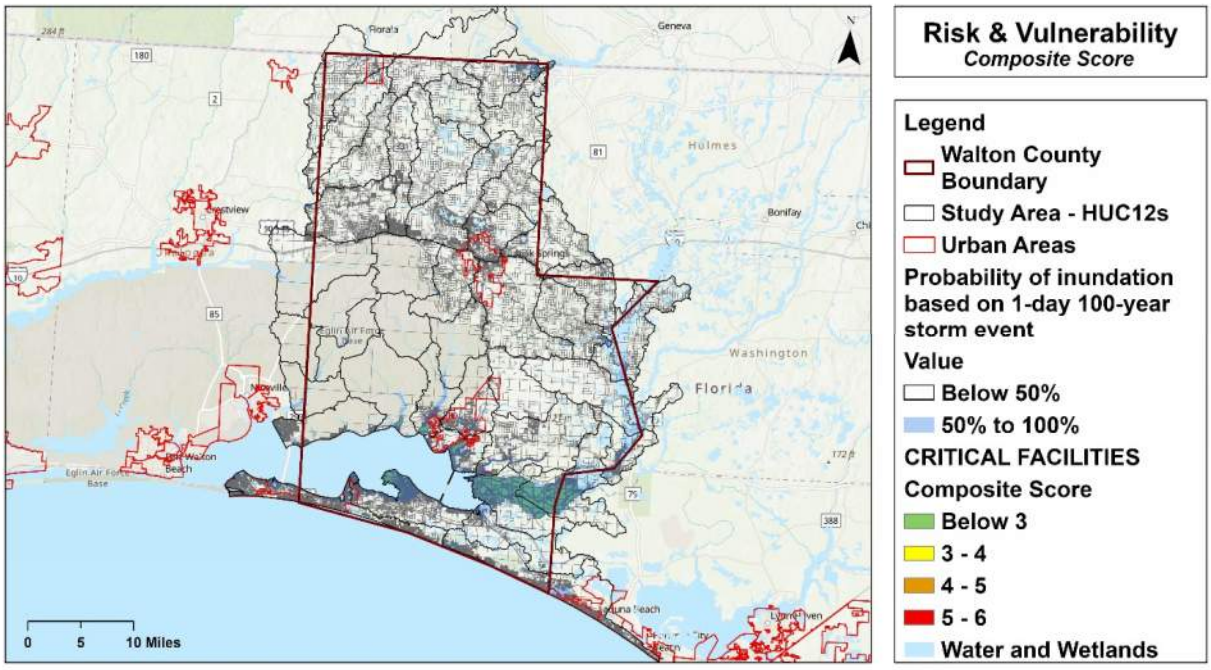

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.
Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

2.4.2 Drill-down – Paxton

For enhanced visualization of the urban areas within this HUC 031401030603, Figure 40 to Figure 42 illustrate the same results for critical facilities (land use priorities) and composite scores, but on a reduced scale, which better facilitates the examination of finer details within the urban area (Paxton). These maps cover both the 1-day 100-year scenario. Sea level rise scenarios were not calculated due to the basin's non-coastal location and high elevation. The composite score results is null, since the town does not experience any flooding.

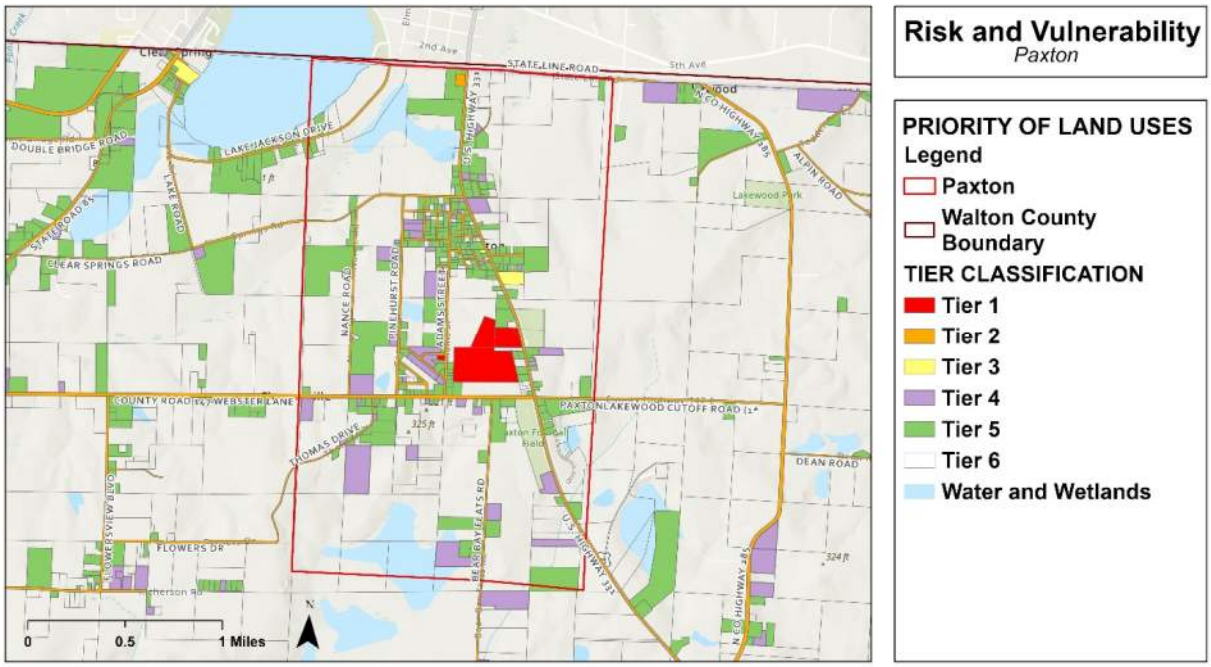

Figure 40. Critical Facilities (priority of land uses) map for Paxton. Processed by FAU.

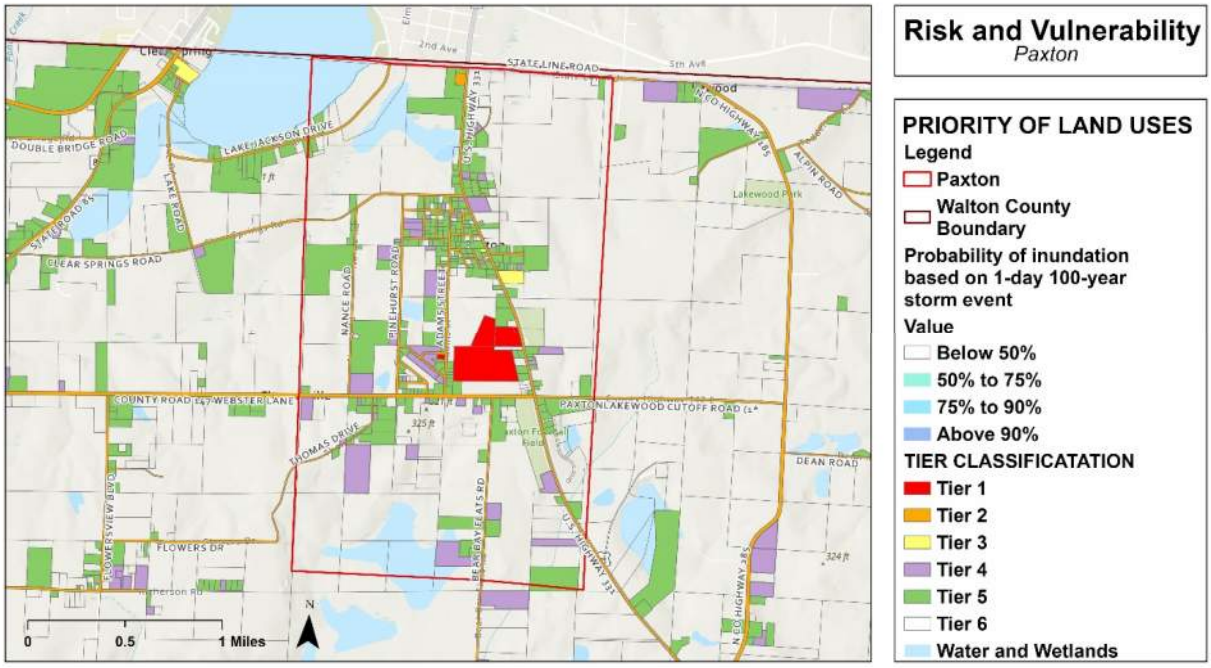

Figure 41. Critical Facilities (priority of land uses) map overlaid in the 1-day 100-year storm event for Paxton. Processed by FAU.

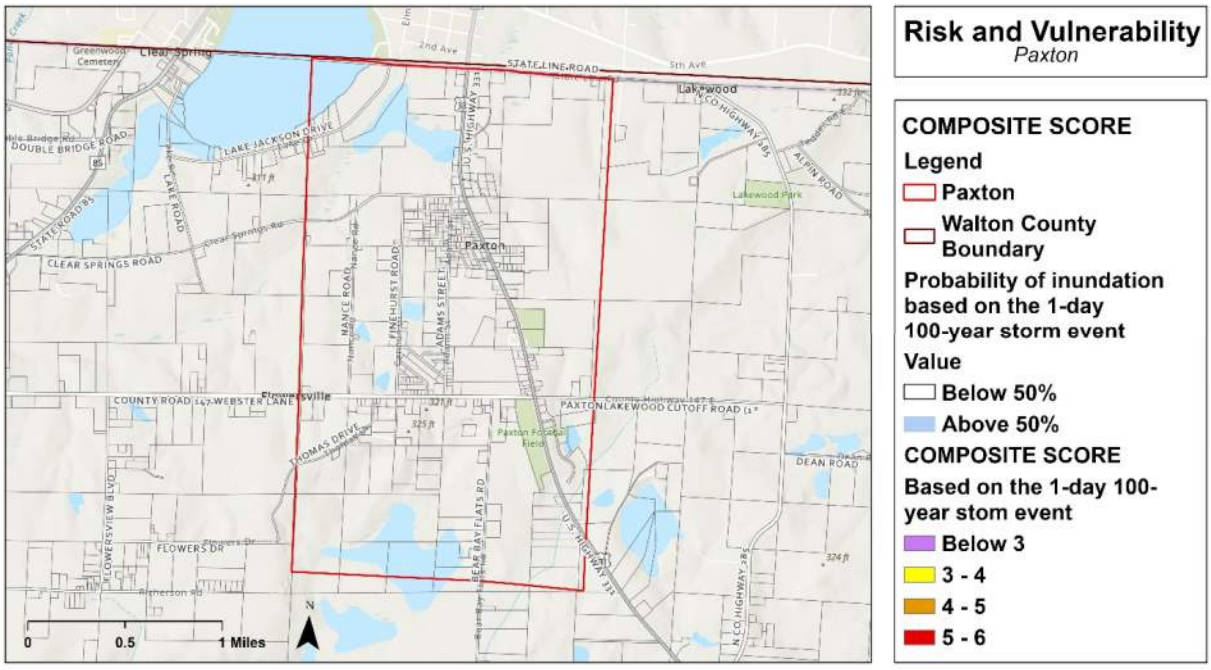

Figure 42. Composite Score map based on 1-day 100-year storm event, overlaid in flooding layer for Paxton. Processed by FAU.

2.4.3 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030603. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.4 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space – see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030603. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030603	21007.62
All of the 1-day 100-year storm event inundation	**24.47**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	24.47
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	24.47

2.4.5 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

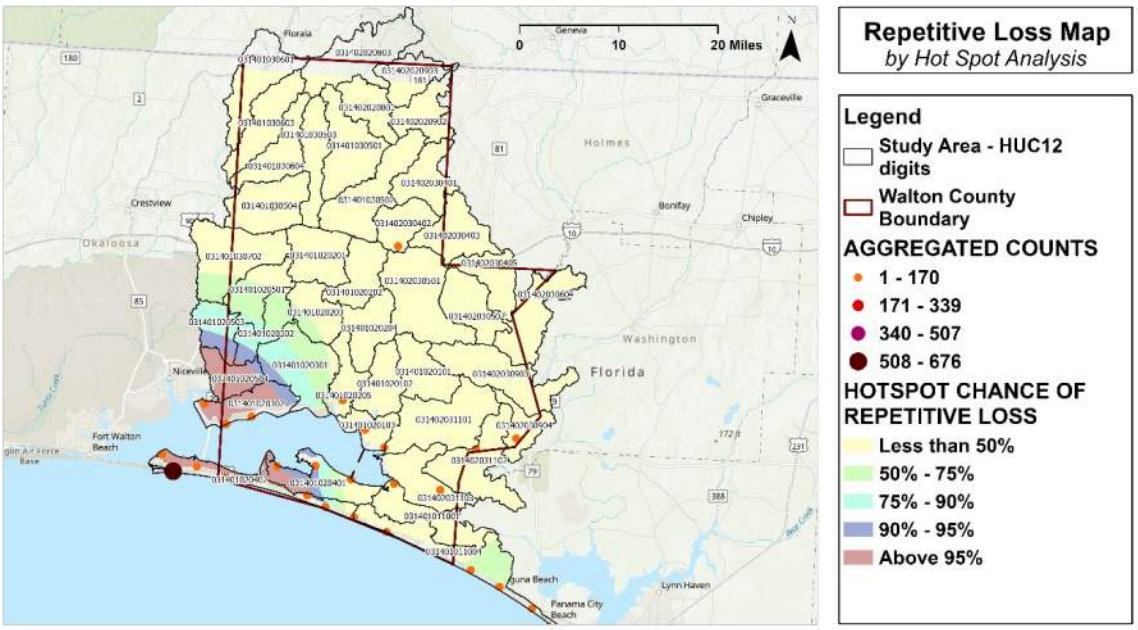

Figure 43. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.6. Priority Projects

Although there is one parcel falling within classification tier 1, and some parcels falling within tiers 2 (roads), 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding in the area is minor and not alarming. Consequently, when considering the composite score, it is notable that the results are null, indicating no priority for intervention within the basin.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030604) is highlighted among all the HUCs to help identifying its location. (Figure 3).

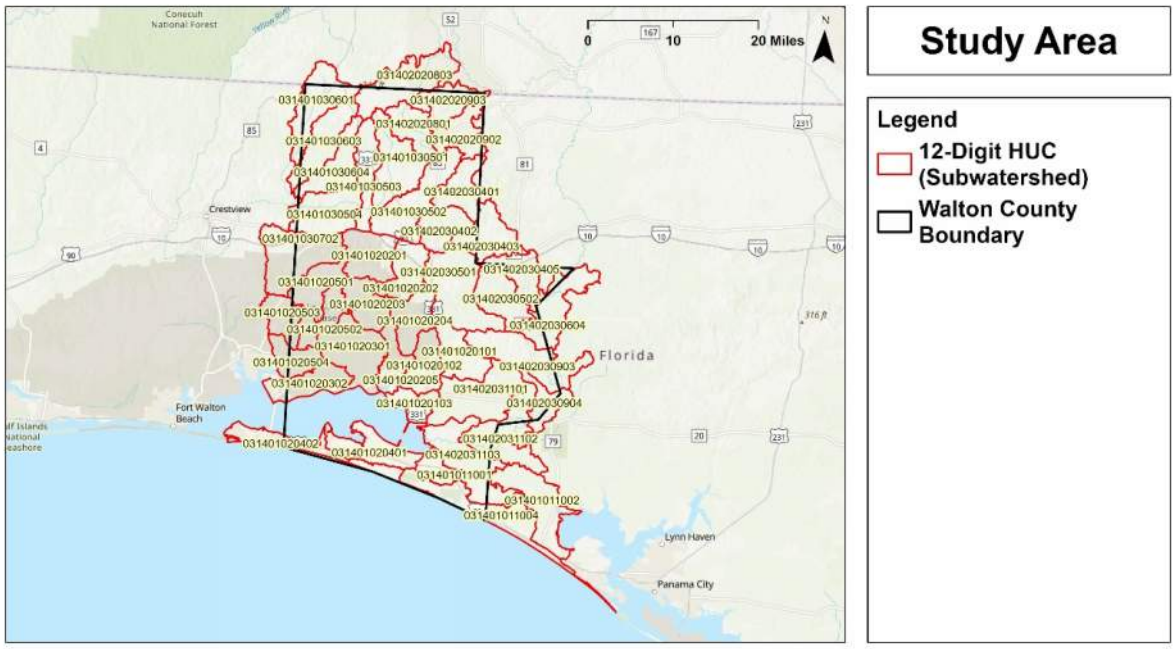

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

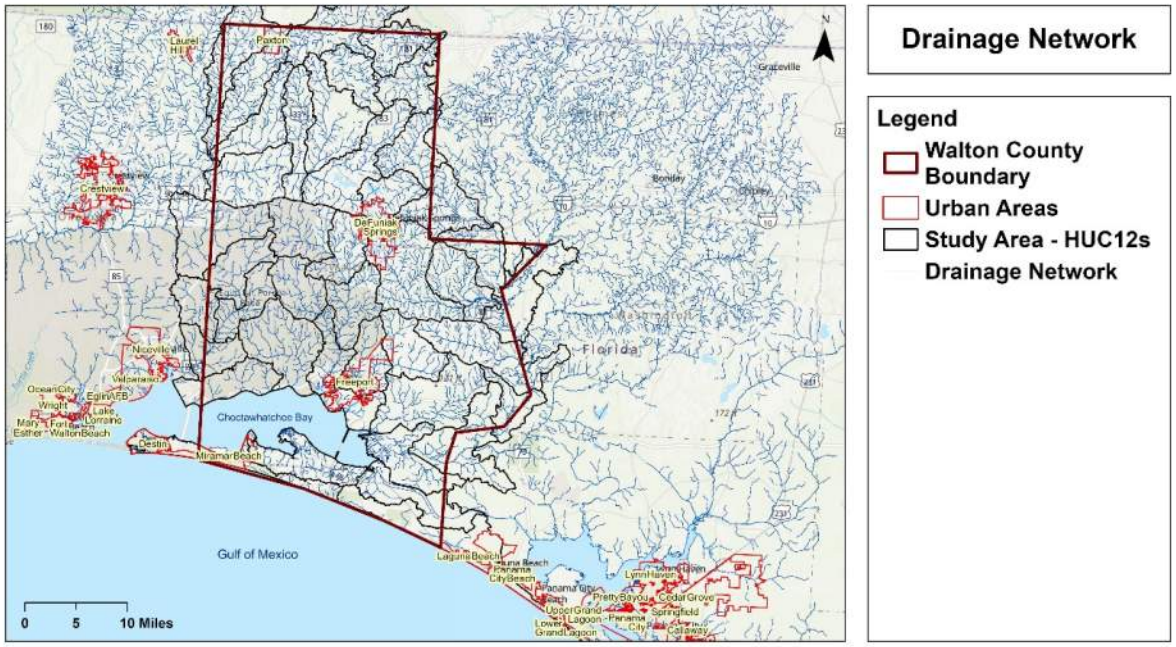

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

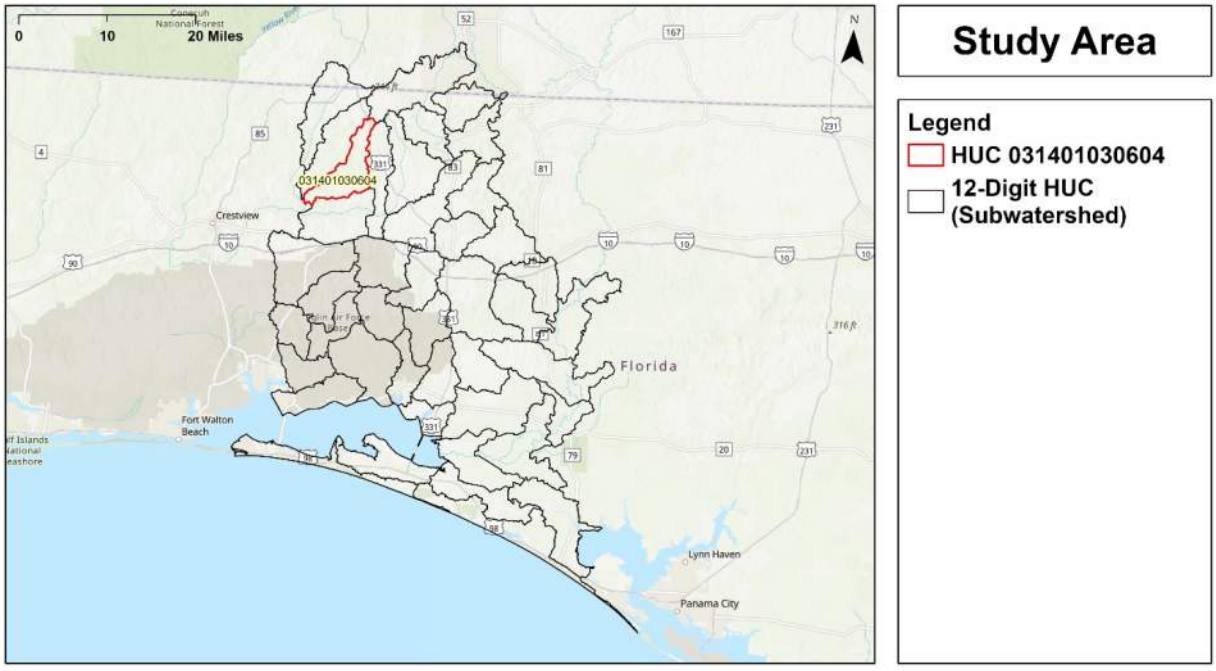

Figure 3. HUC 031401030604 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering

diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	Community Name	CRS Class Rating	Premium Discount for SFHA	% Discount for Non- SFHA	Status
120317	Walton County	6	20%	10	Cycle

Based on the future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land use table for Walton County (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	Area (Acres)	Percentage of Total
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 2.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with

high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

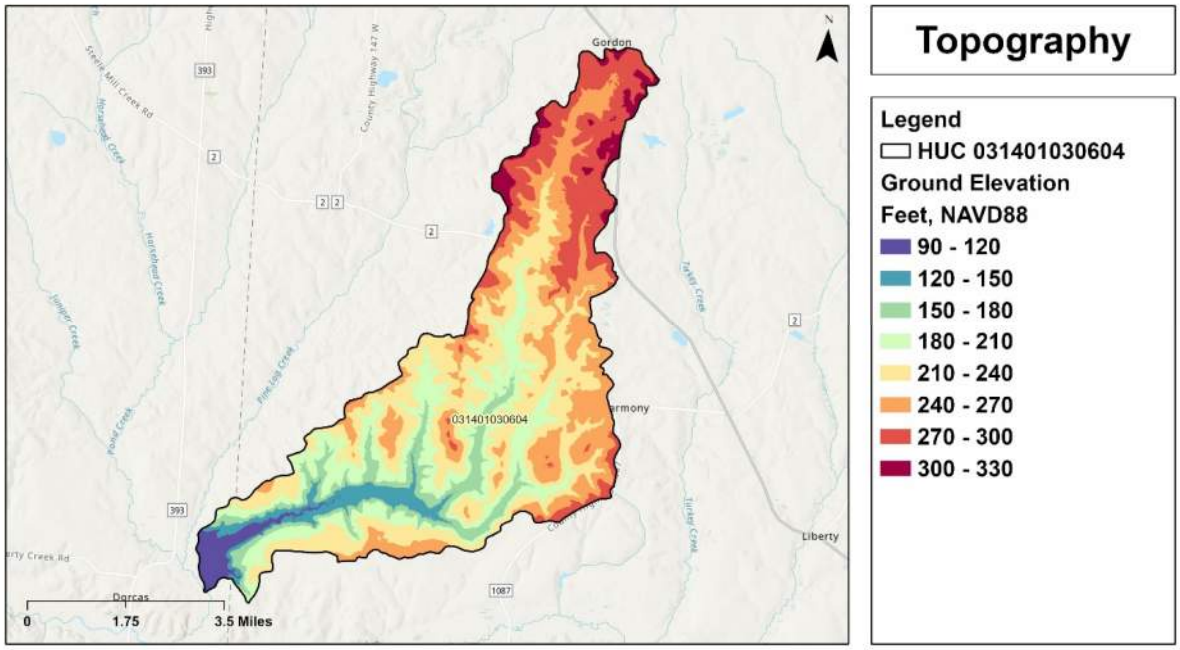

Figure 4. Topographic map of the HUC 031401030604 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of

wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030604 sub-watershed is shown in **Error! Reference source not found.**.

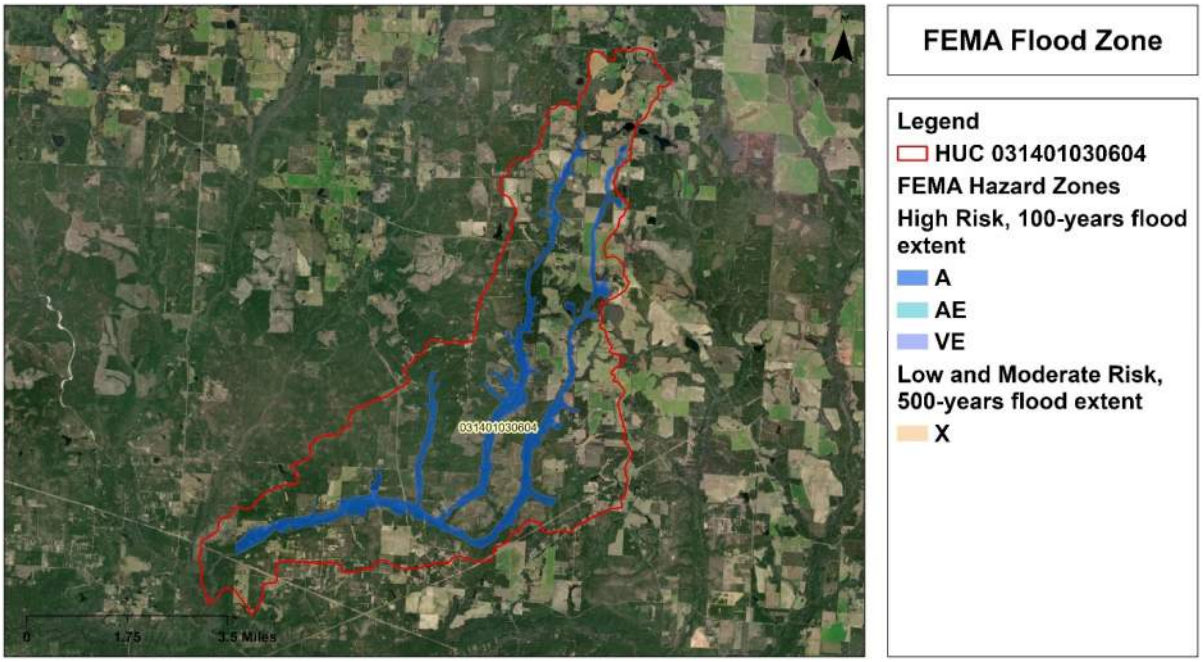

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030604 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal

area, including the sub-watershed 031401030604 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

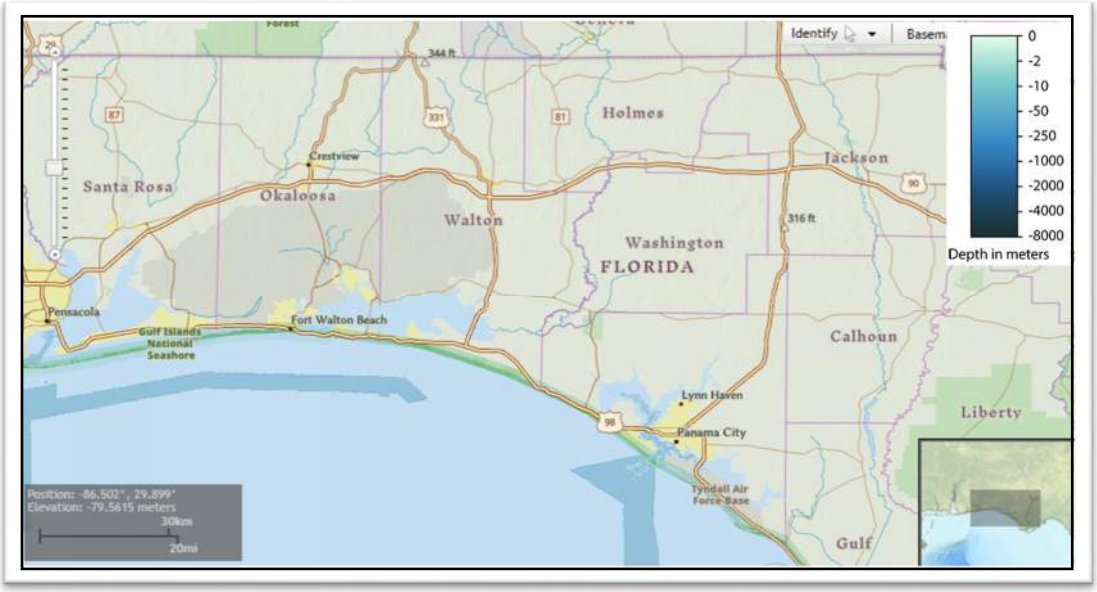

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological

conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

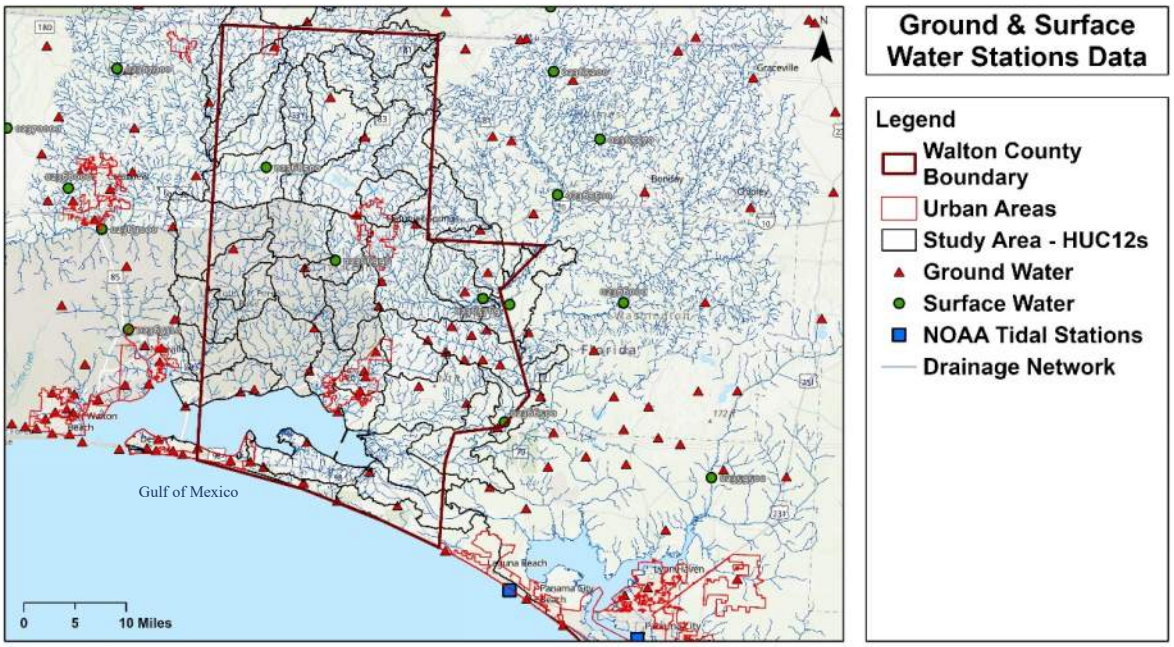

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030604 has no major rivers and canals, but creeks, include:

- Long Creek
- Little Creek
- Beech Tree Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030604, which is USGS 02368500 Shoal River.

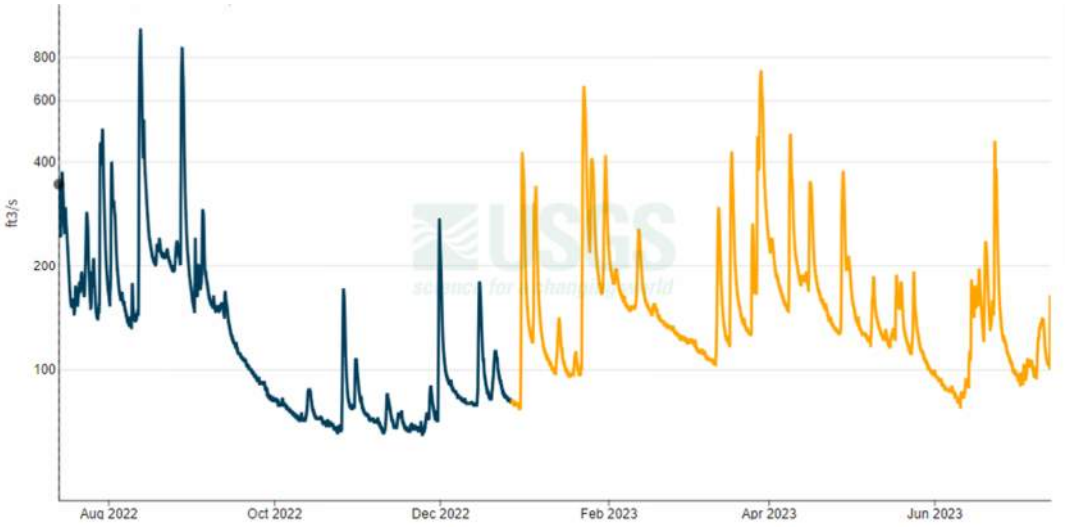

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the rivers and streams to establish points for a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The topography and points where streams join form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030604 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401030604 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

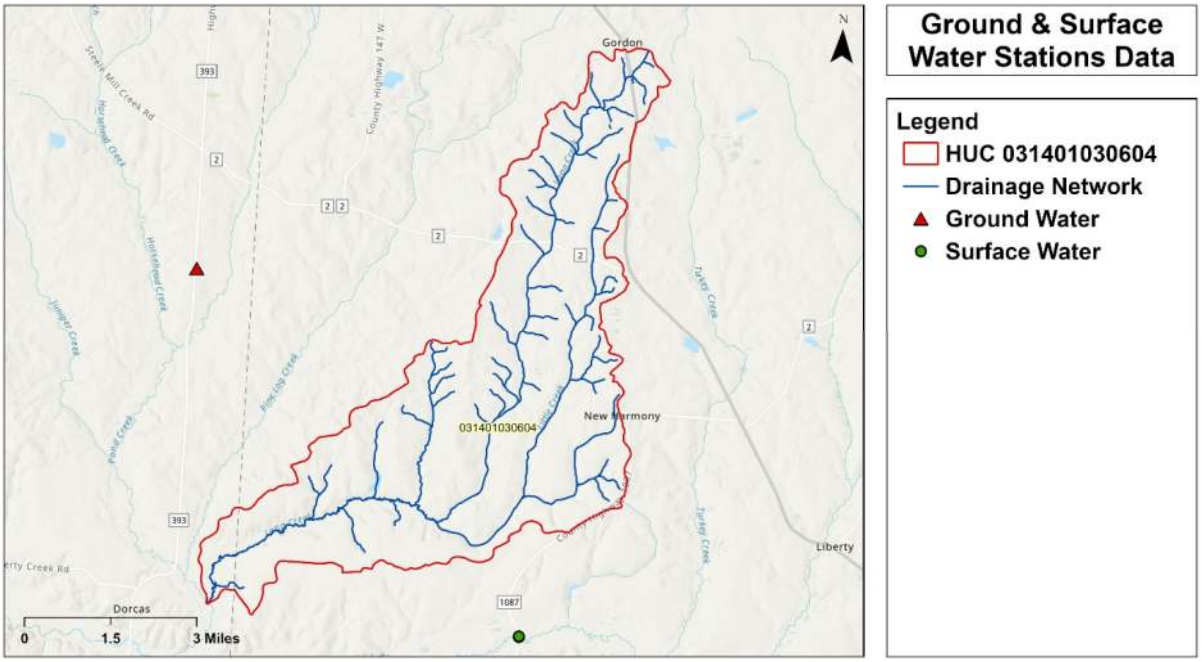

Figure 9. Ground and Surface Water Stations in the HUC 031401030604 sub-watershed, processed by FAU.

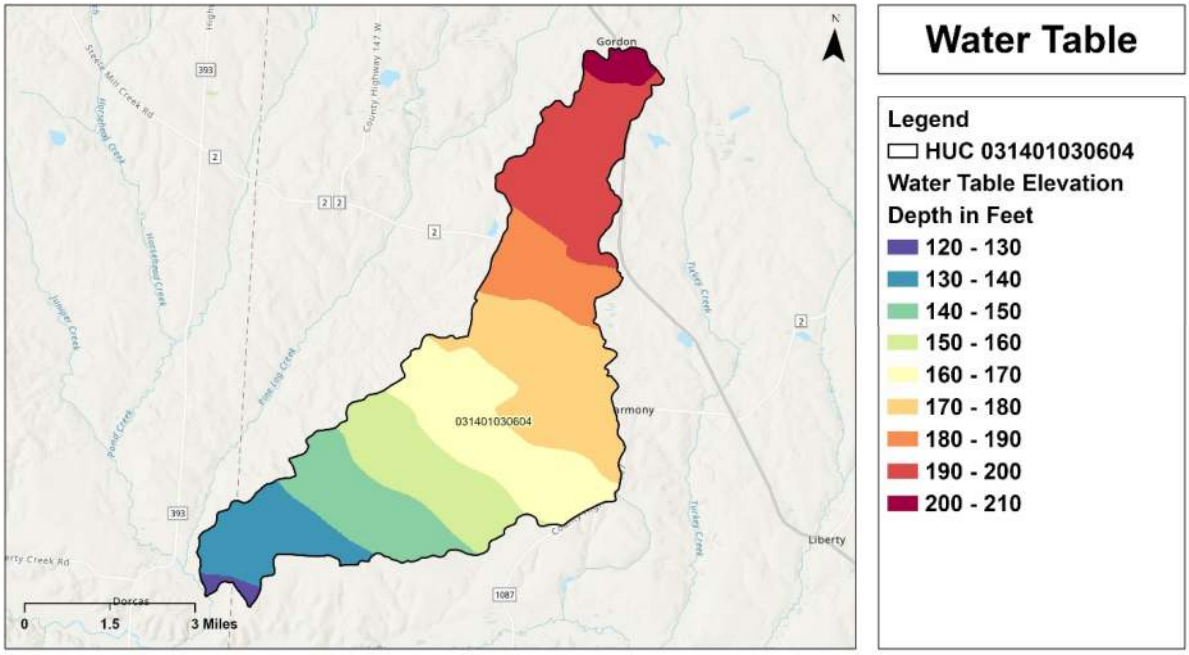

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030604 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the observed rainfall over Walton County for every month between 1900 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches, for the entire county.

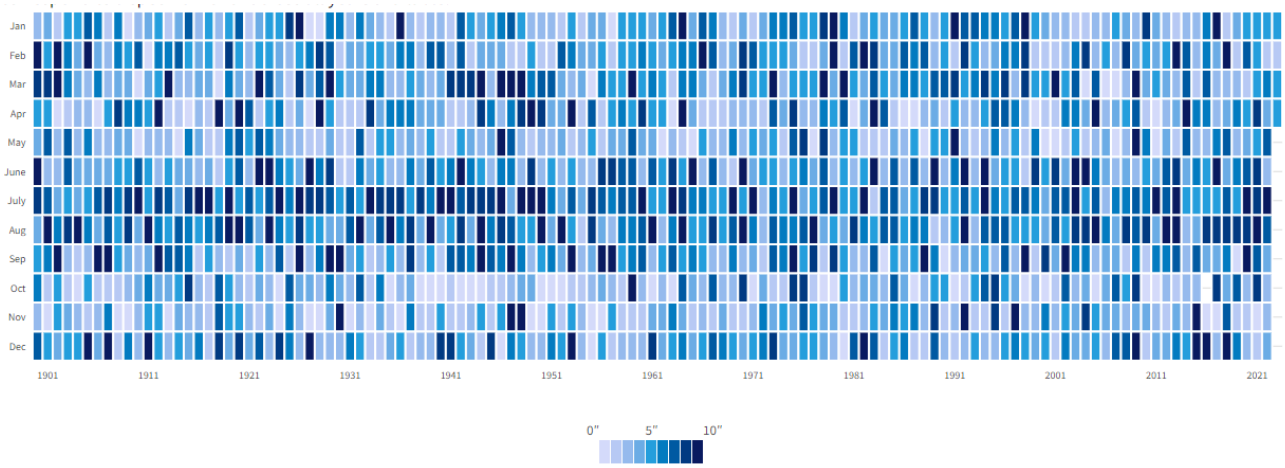

Figure 11. Monthly precipitation in Walton County, FL.
Source: National Centers for Environmental Information
(https://usafacts.org/issues/climate/state/florida/county/walton-county/#precipitation/)

While the topography (Section 2.1) and native soil (Section 2.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

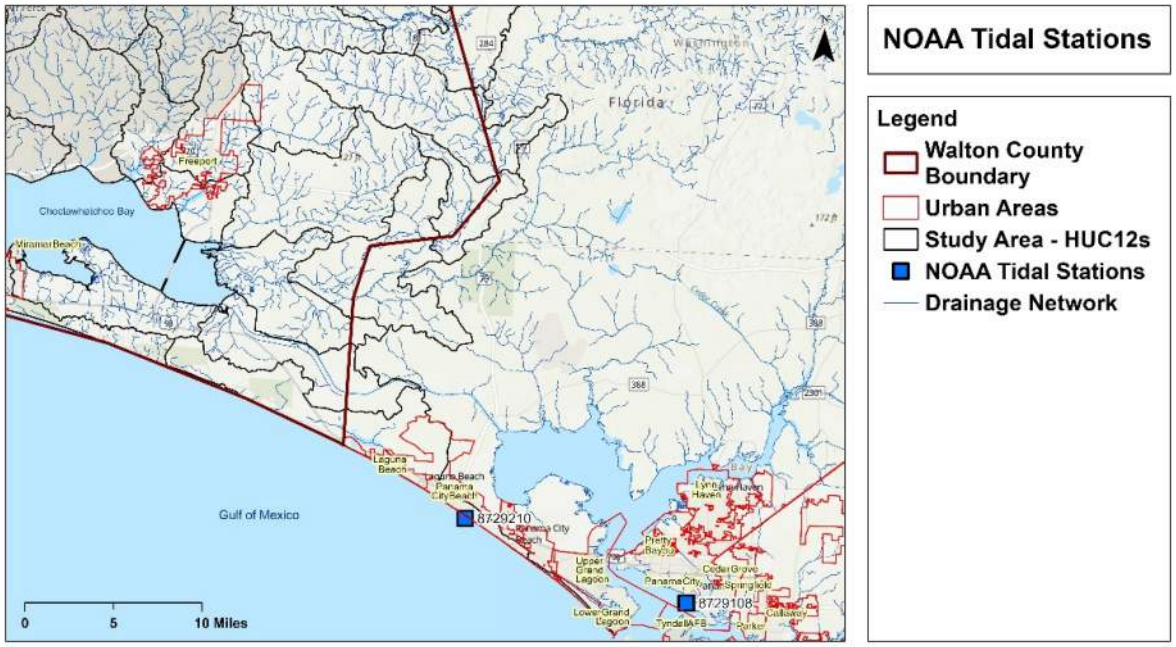

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

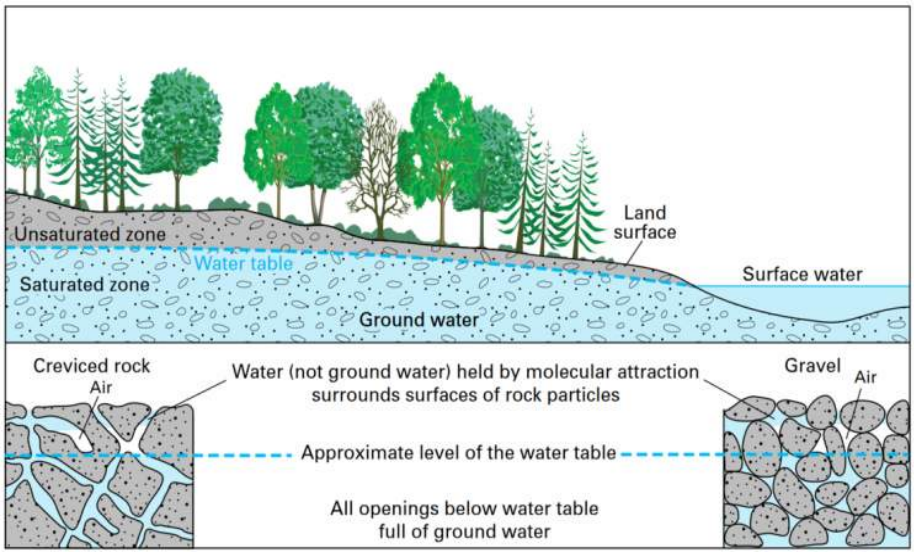

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

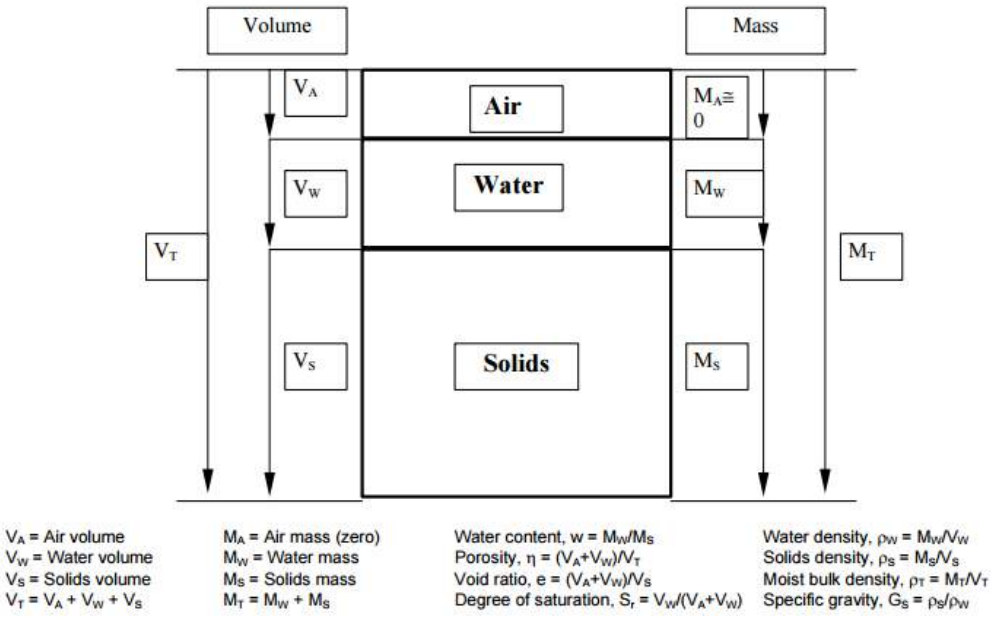

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

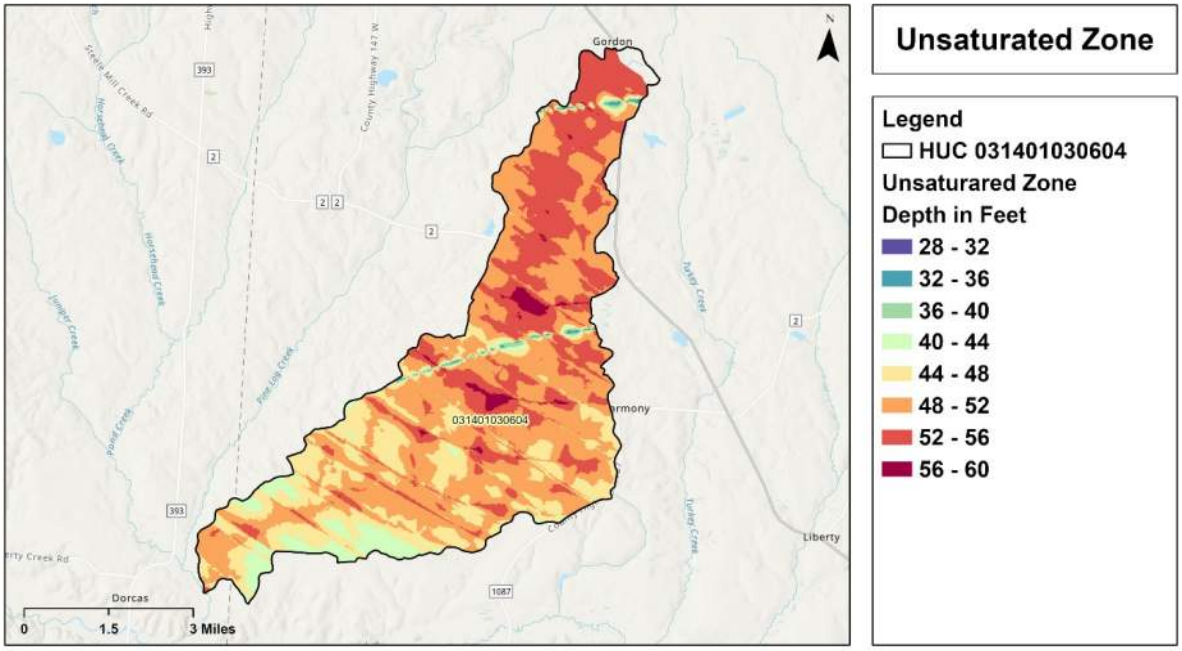

Figure 15. Unsaturated zone map for HUC 031401030604, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A great portion of the basin has enough soil storage capacity, ranging between 44 to 60 inches of capacity left.

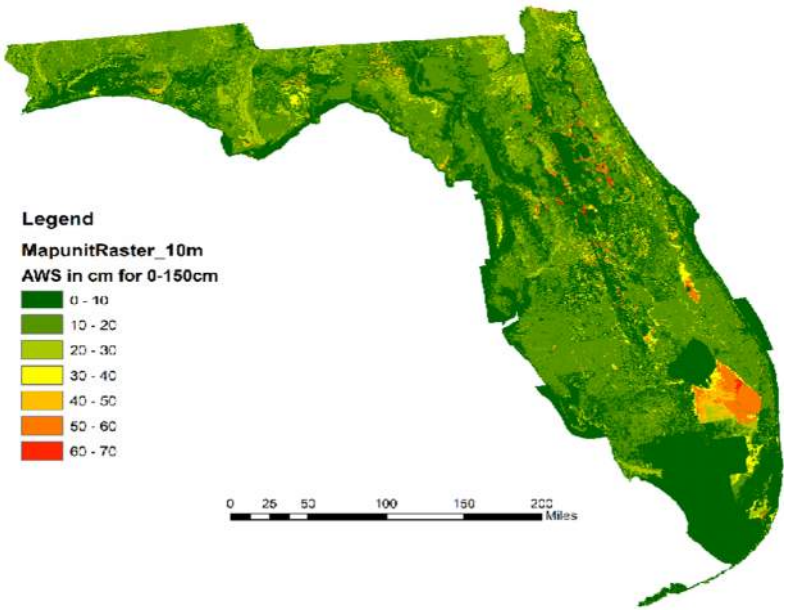

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, processed by FAU.

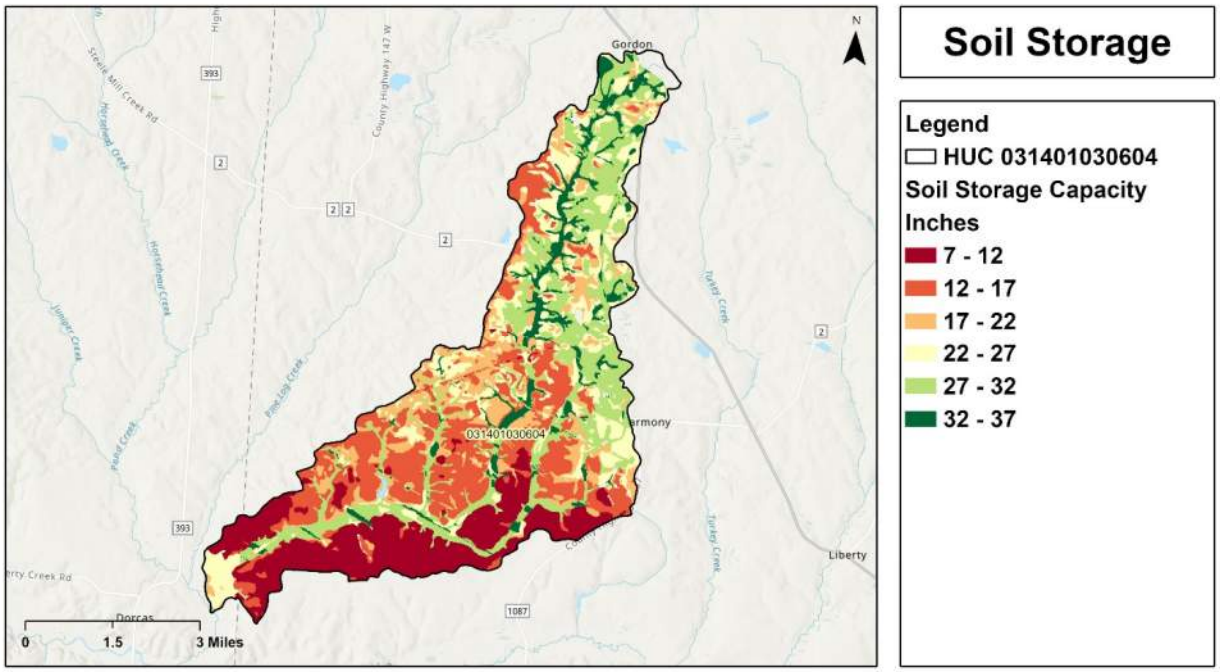

Figure 17. Water storage capacity of soil for the HUC 031401030604, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

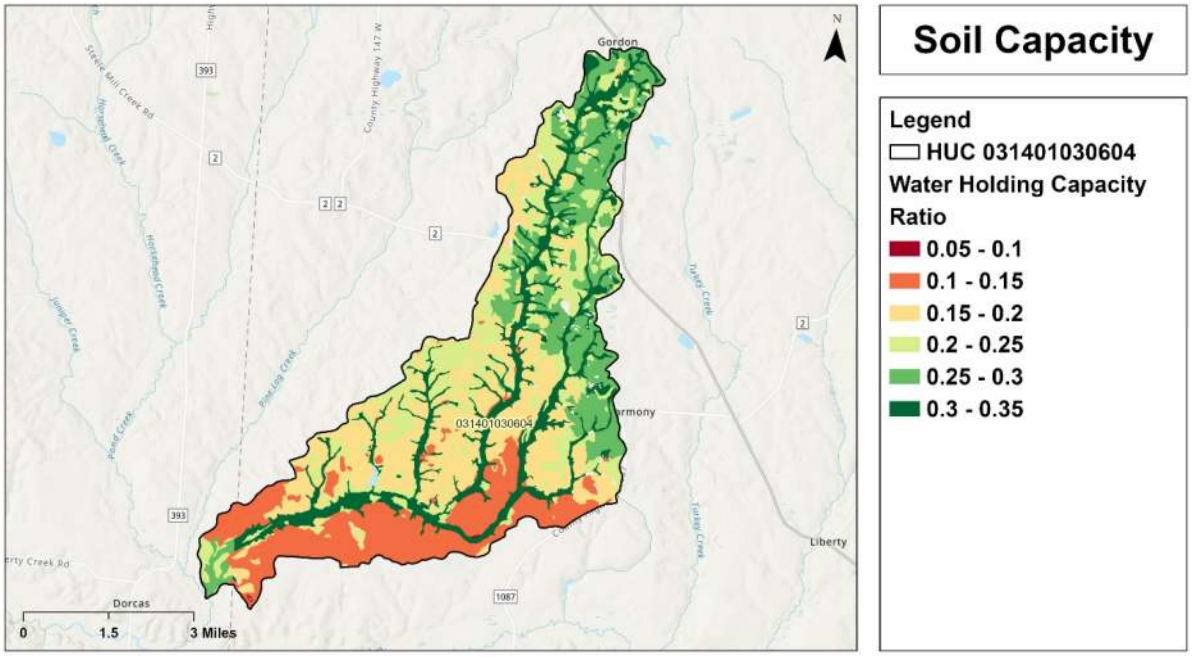

Figure 18. Water Holding Capacity (ratio) for the HUC 031401030604, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

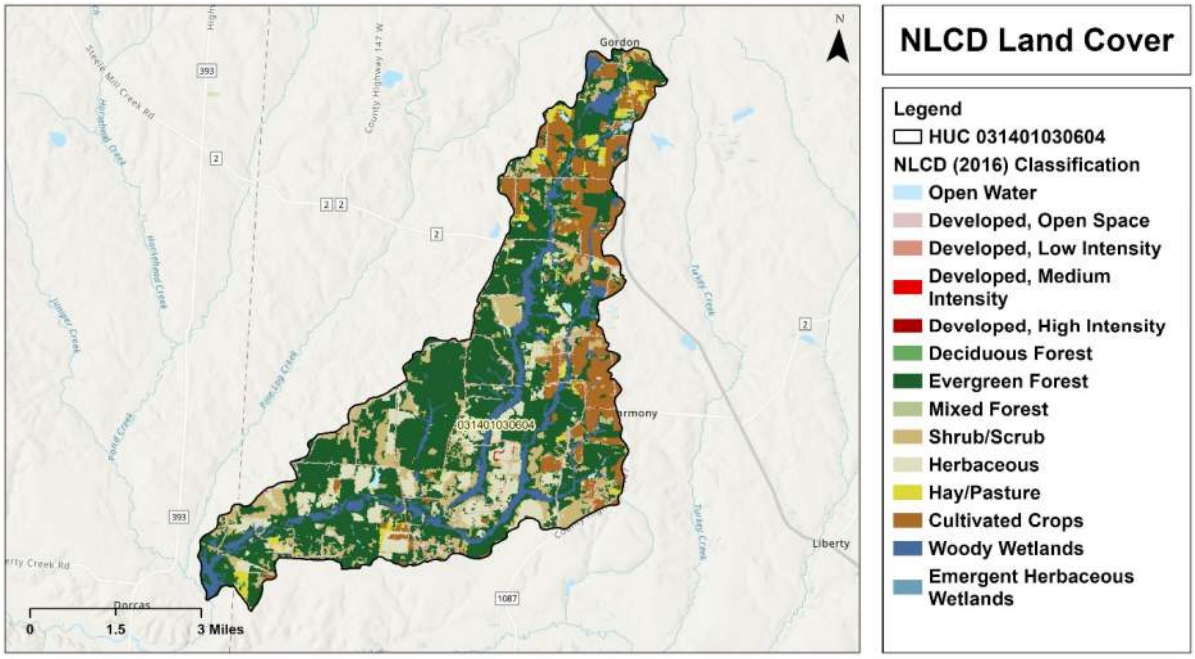

Figure 19. Land use in the HUC 031401030604 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps were used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

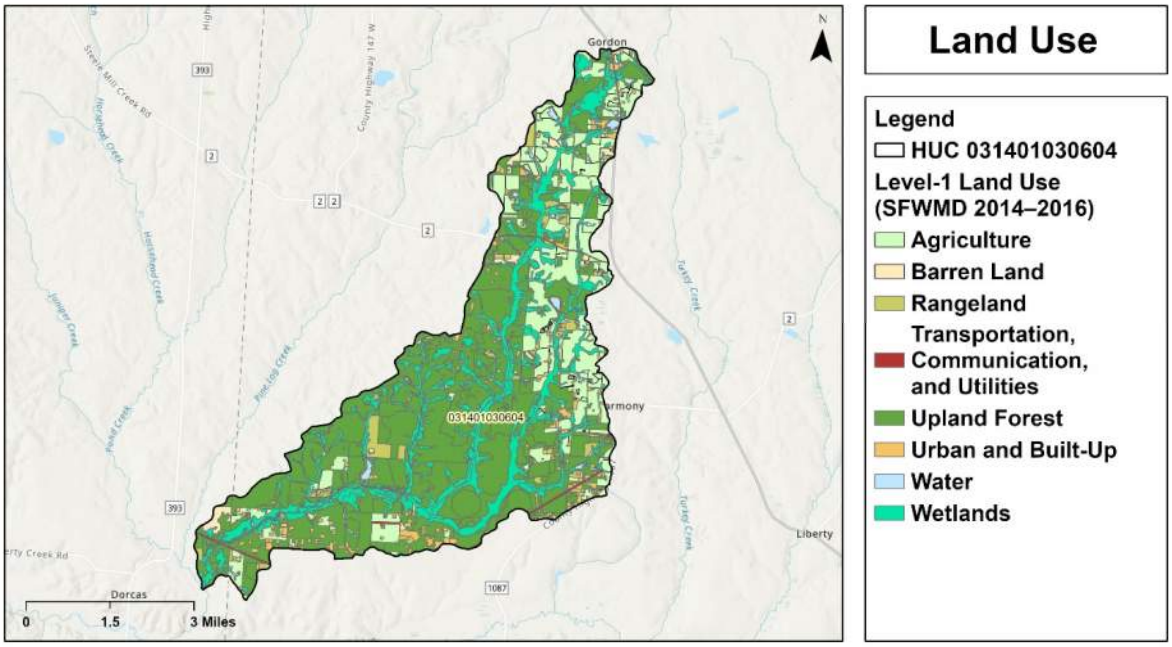

Figure 20. Land use in the HUC 031401030604 (023 Florida Geographic Data Library (FGDL)), processed by FAU.

In the HUC 031401030604 sub-watershed, mostly of the area is upland forest, with 55.30%. The second place is agriculture, with 18.32%, followed by wetlands, with 15.45%. There is no much developed land in the HUC – only 3.32% is urban and built-up and 1.45% is Transportation, Communication, and Utilities, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030604 subwatershed (023 Florida Geographic Data Library (FGDL)).

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	4428.75	18.32%
Barren Land	252.68	1.05%
Rangeland	690.51	2.86%
Transportation, Communication, and Utilities	350.85	1.45%
Upland Forest	13368.33	55.30%
Urban and Built-Up	802.06	3.32%
Water	545.24	2.26%
Wetlands	3735.38	15.45%
Grand Total:	**24173.81**	**100.00%**

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

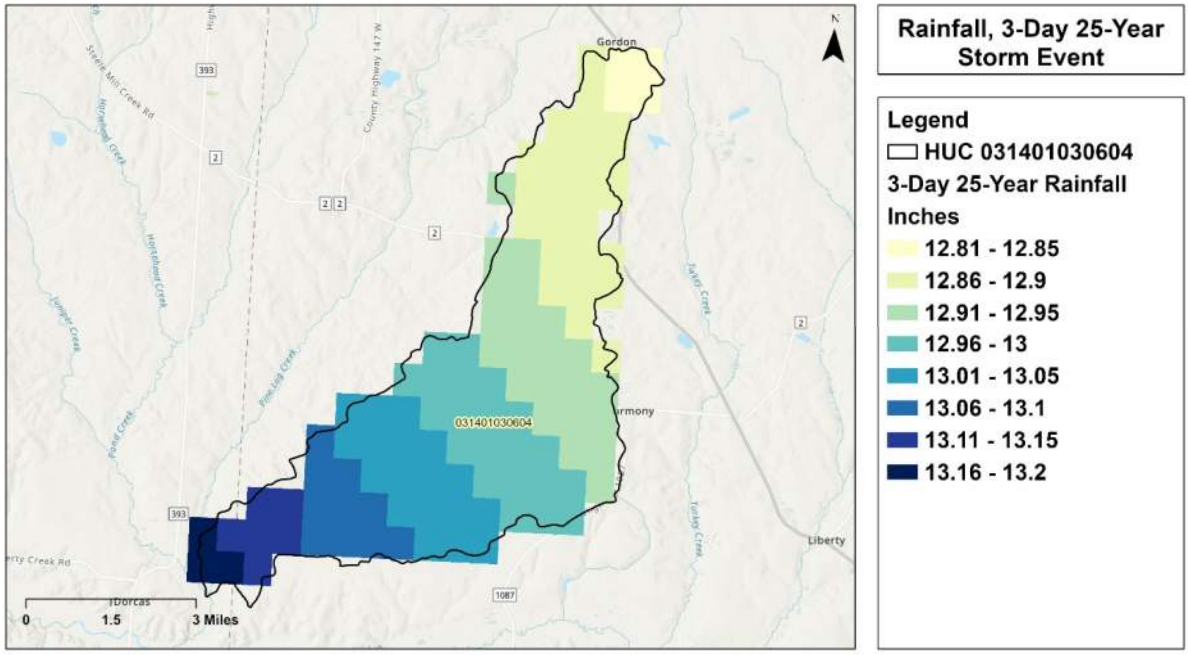

Figure 21. Rainfall distribution map across HUC 031401030604 sub-watershed, for 3-day 25-year storm event, processed by FAU.

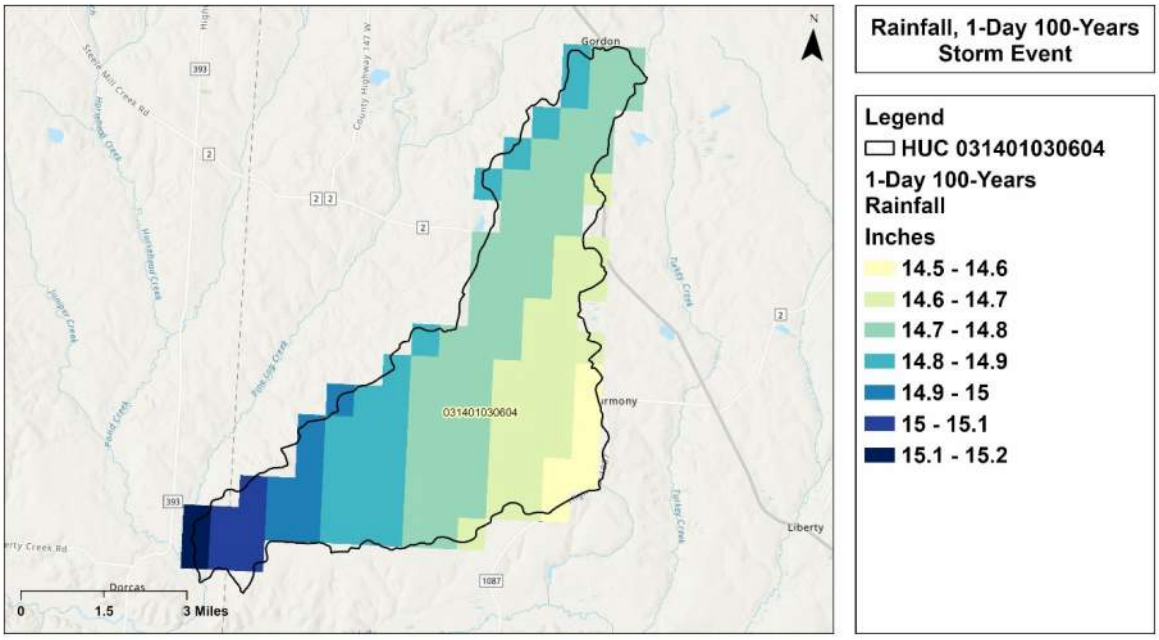

Figure 22. Rainfall distribution map across HUC 031401030604 sub-watershed, for 1-day 100-year storm event, processed by FAU.

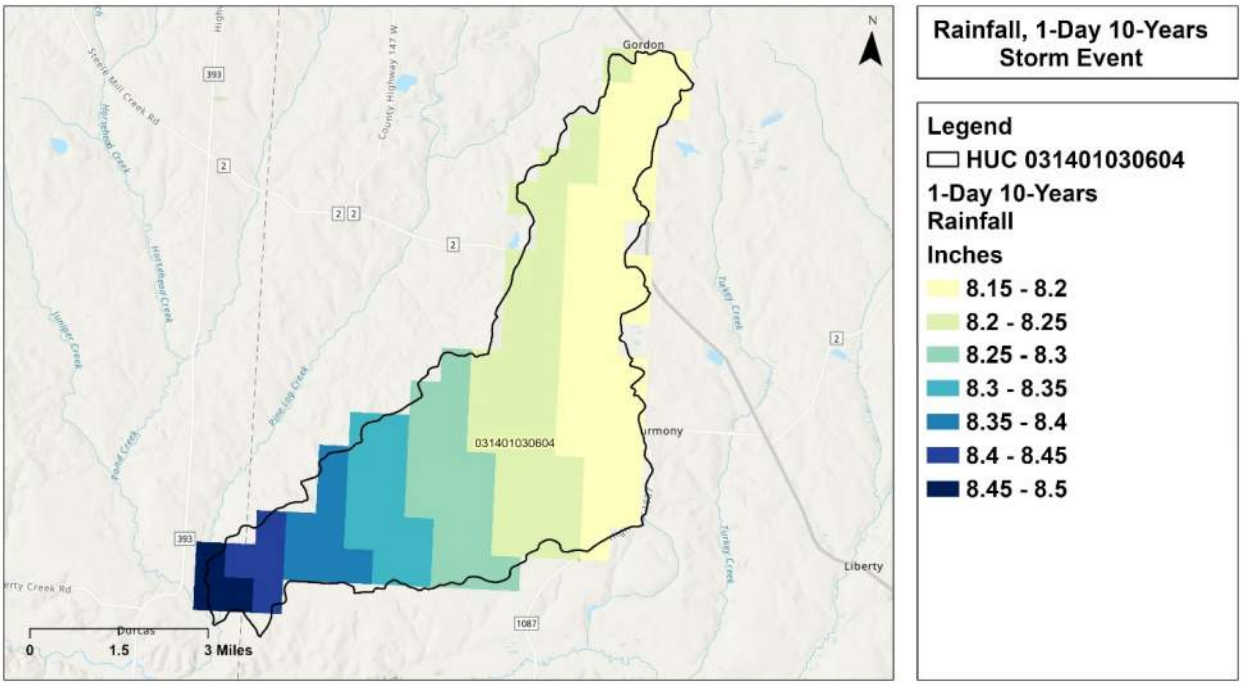

Figure 23. Rainfall distribution map across HUC 031401030604 sub-watershed, for 1-day 10-year storm event, processed by FAU.

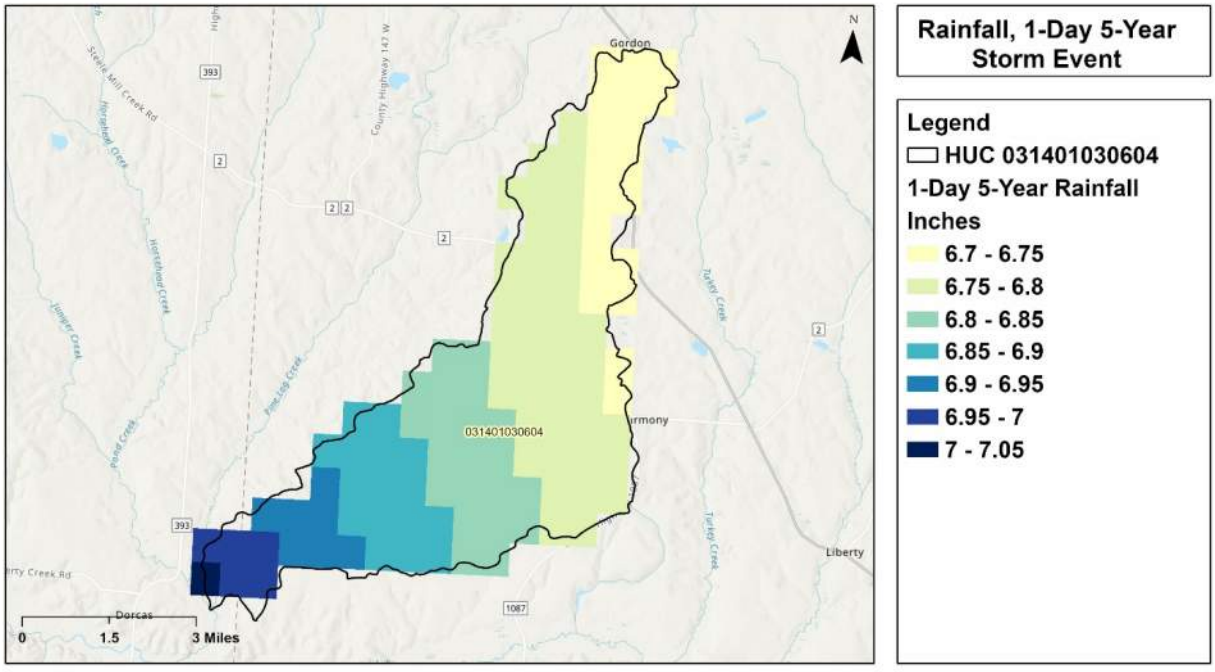

Figure 24. Rainfall distribution map across HUC 031401030604 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

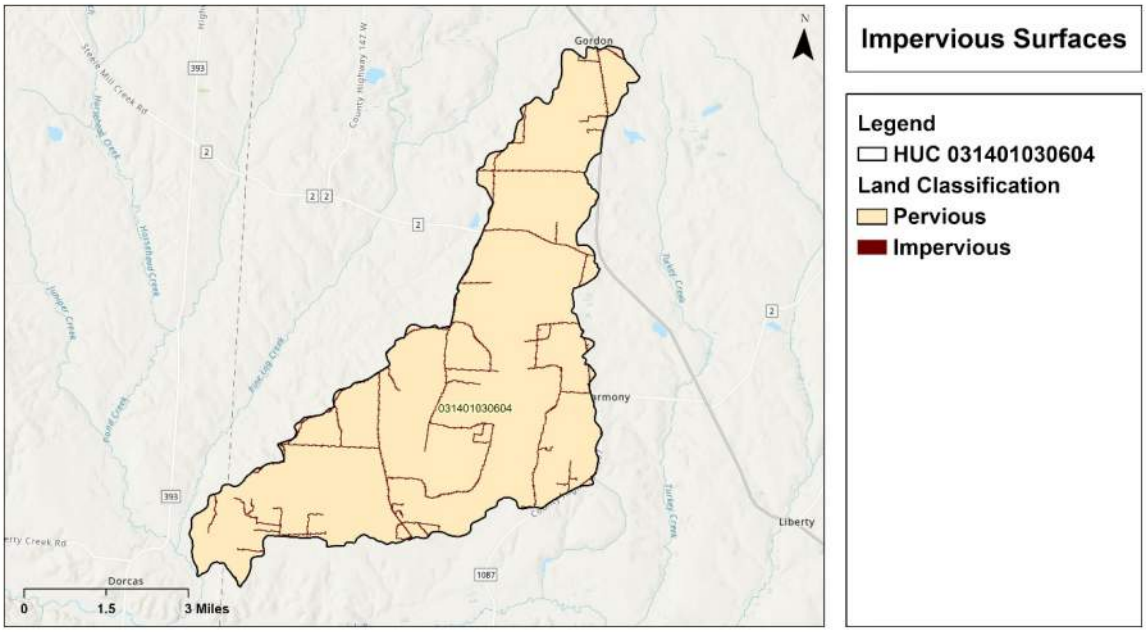

Figure 25. Impervious area map for the HUC 031401030604 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

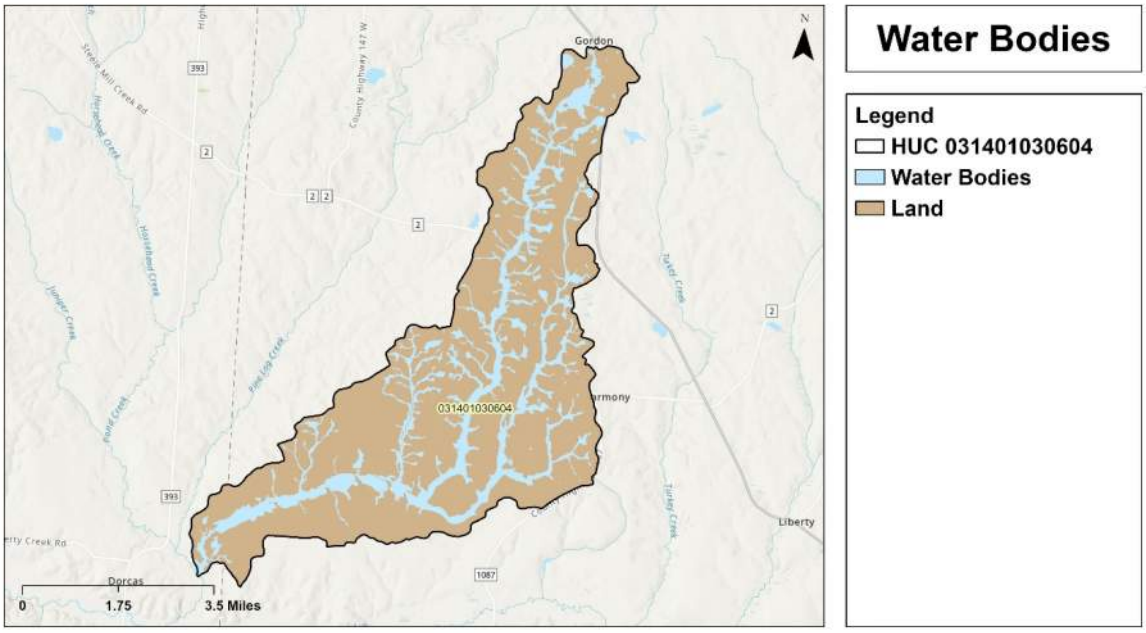

Figure 26. Water bodies map for the HUC 031401030604 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs,

property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.

- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

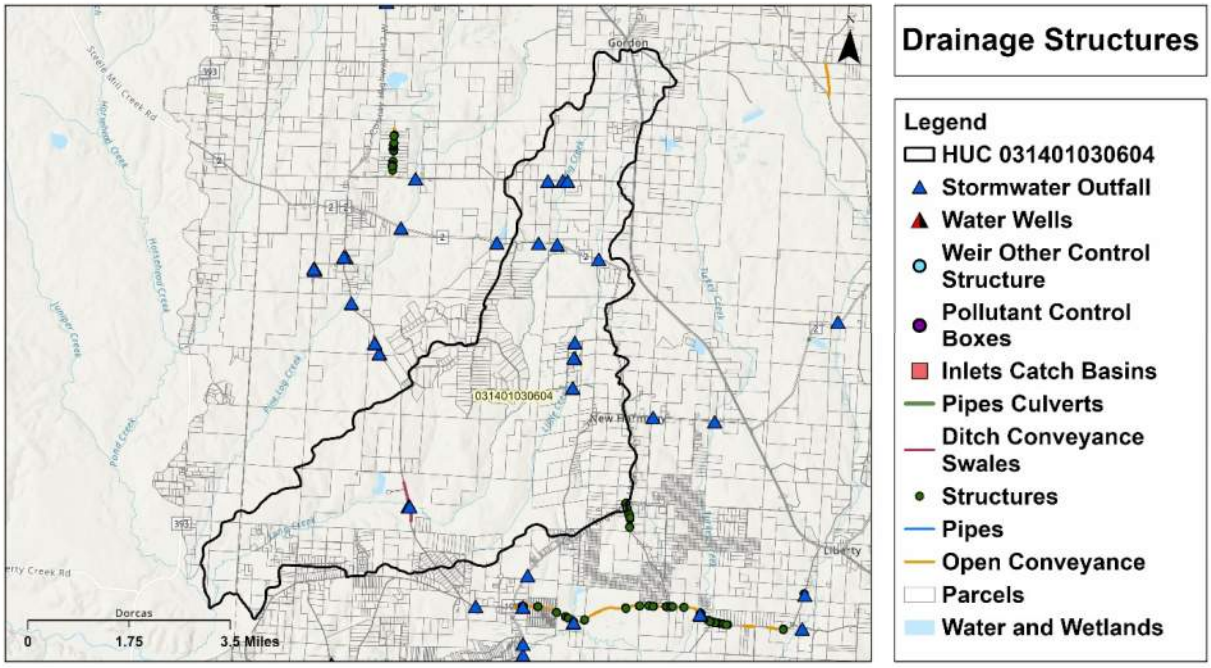

Figure 27. Stormwater Infrastructure for the HUC 031401030604. Processed by FAU.

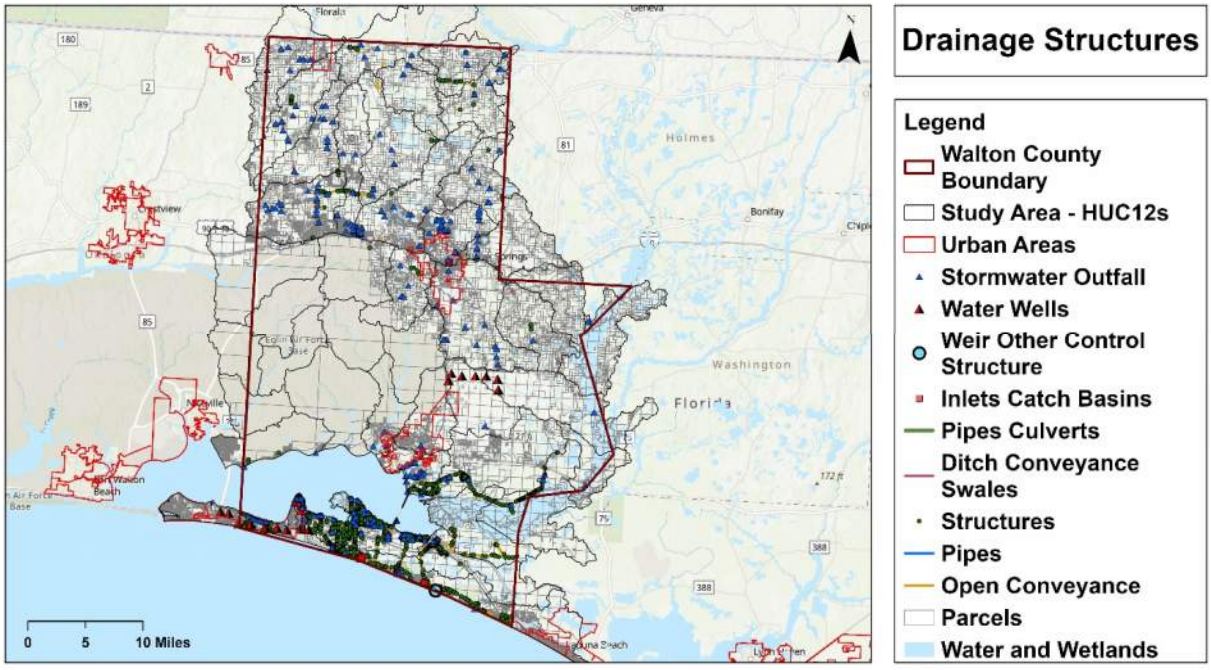

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1 and 2, and comparing to data in Chapter 3, vulnerability can be identified.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030604 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.4.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

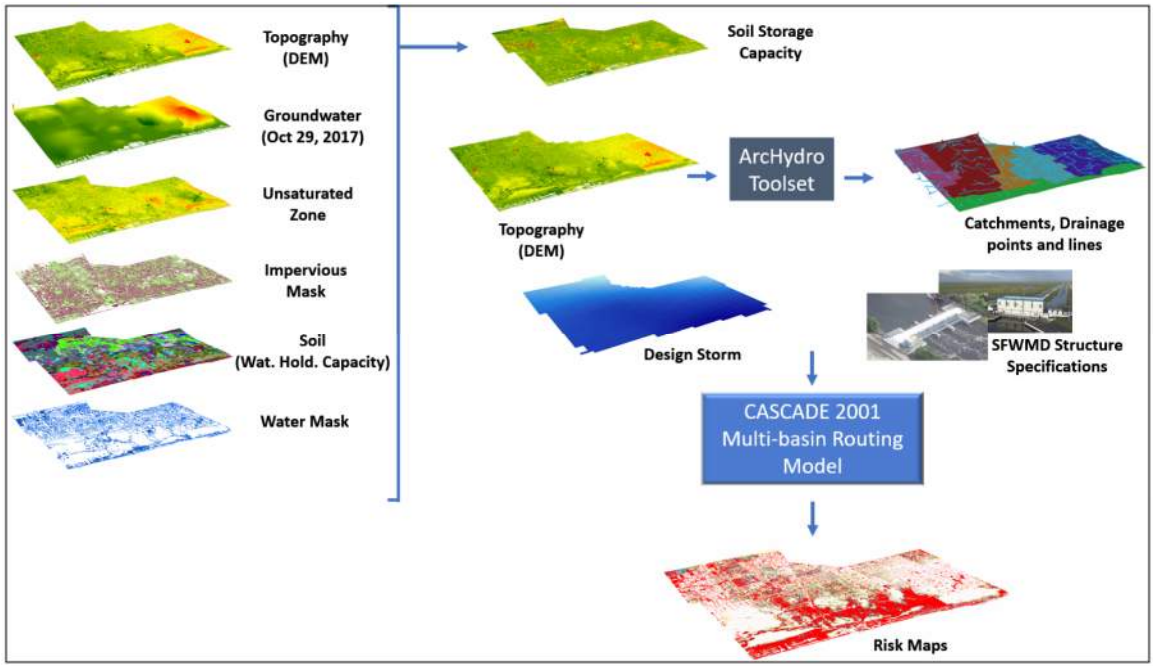

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

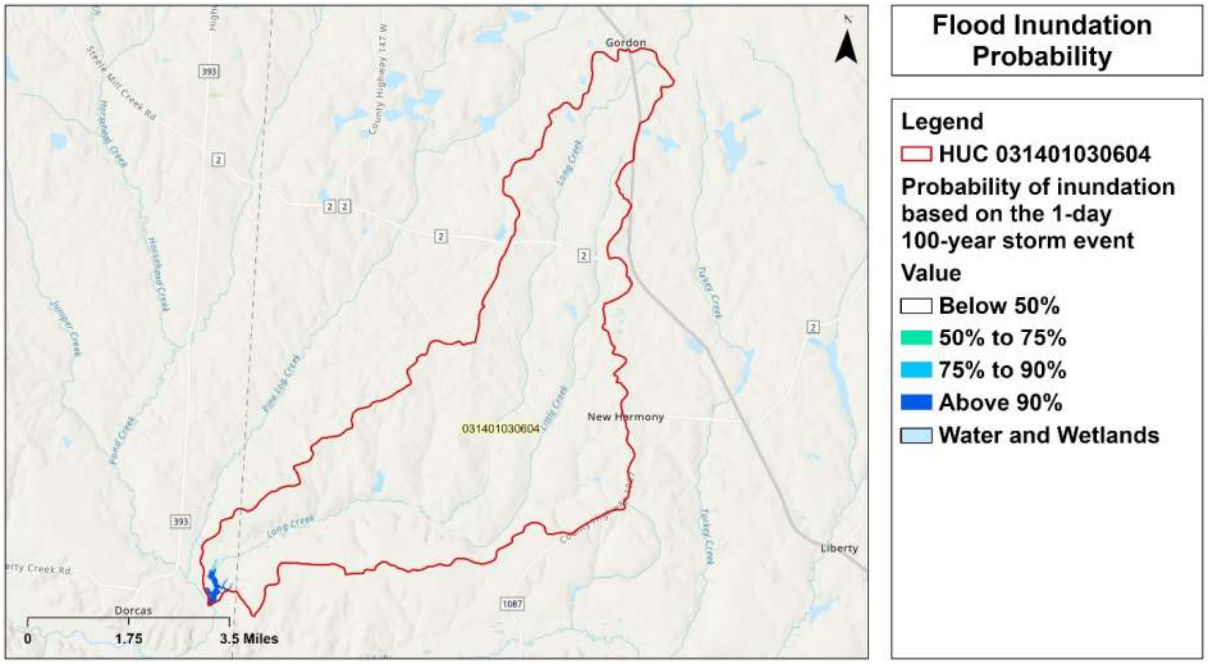

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030604, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

fter this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 5.2 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees

and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding, almost imperceptible, is noted at the creek entrance to the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 0.28% of the HUC total area or only 0.082 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, 0.32% of the HUC's total area, or 0.094 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.26% of the HUC's total area, or 0.075 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.25% of the HUC's total area, or 0.074 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030604 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	29.146	0.082	99.72%	0.28%
1-day 100-year	29.134	0.094	99.68%	0.32%
1-day 10-year	29.153	0.075	99.74%	0.26%
1-day 5-year	29.154	0.074	99.75%	0.25%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older, poor health individuals would have a lower priority than at risk communities, which generally have

lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is

converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401030604 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

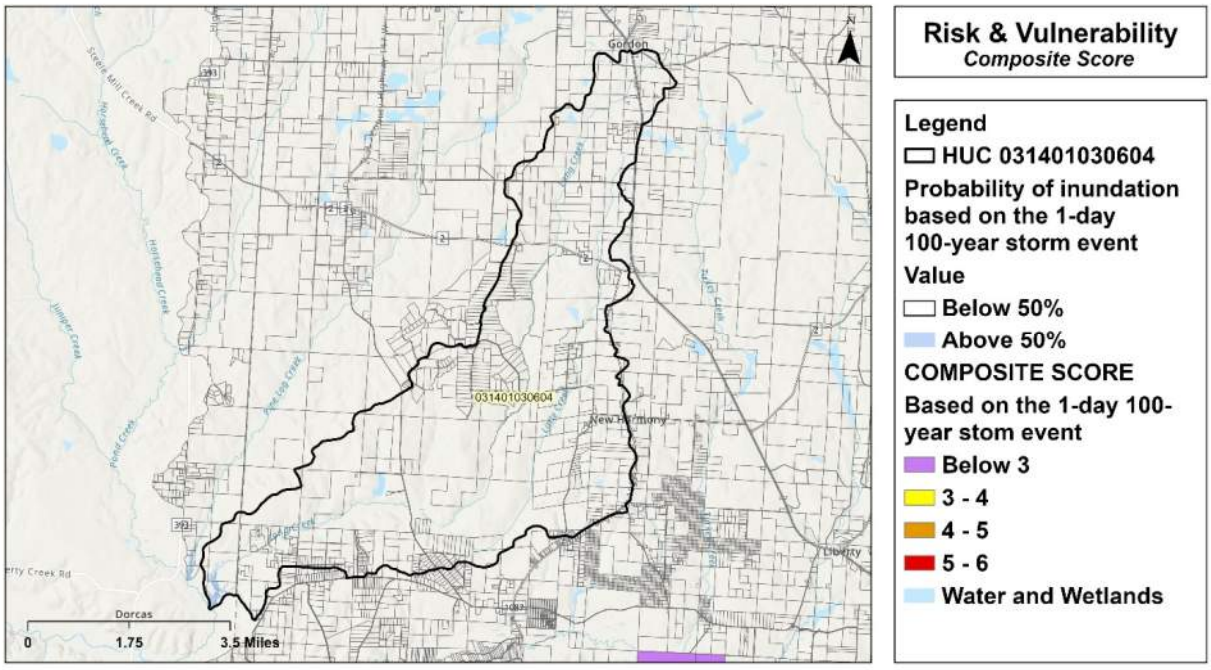

Figure 38. HUC 031401030604 sub-watershed Composite Score Risk map, with calculation based on 1-day 100-year storm event. Processed by FAU.

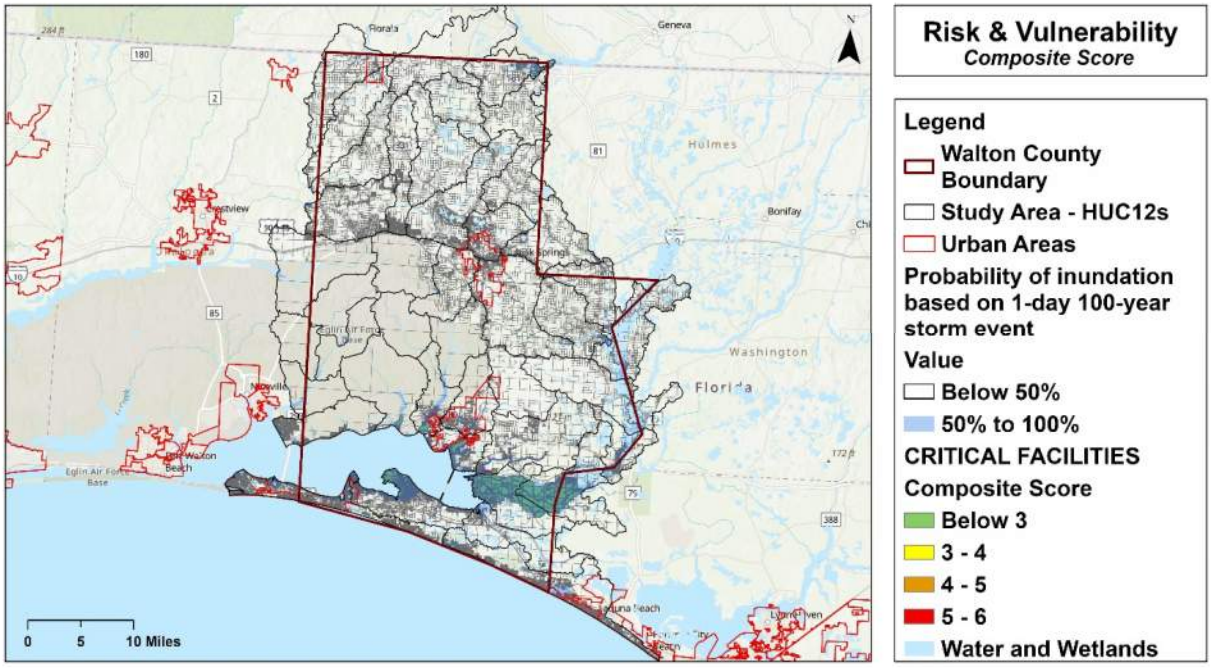

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030604. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands: This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands: In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030604. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030604	18706.20
All of the 1-day 100-year storm event inundation	**60.16**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	60.16
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	60.16

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. . **Error! Reference source**

not found. indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

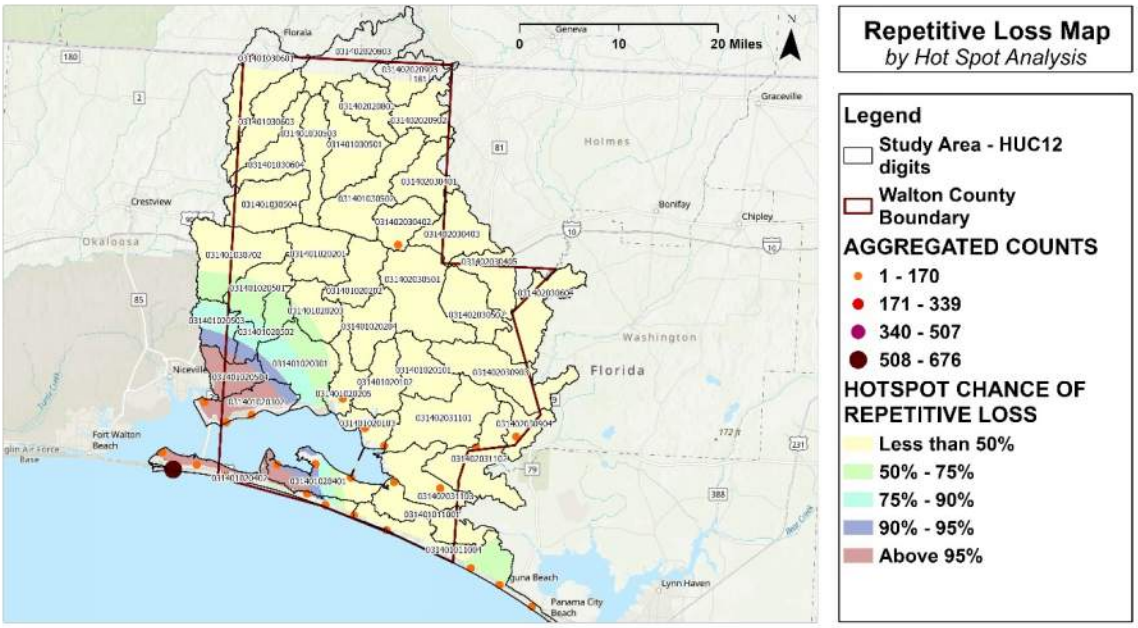

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are some parcels falling within tiers 2 (roads), 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding in the area is minor and not alarming. Consequently, when considering the composite score, it is notable that the results are null, indicating no priority for intervention within the basin.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 sub-watershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 digits (031401030702) is highlighted among all the HUCs to help identify its location. (Figure 3).

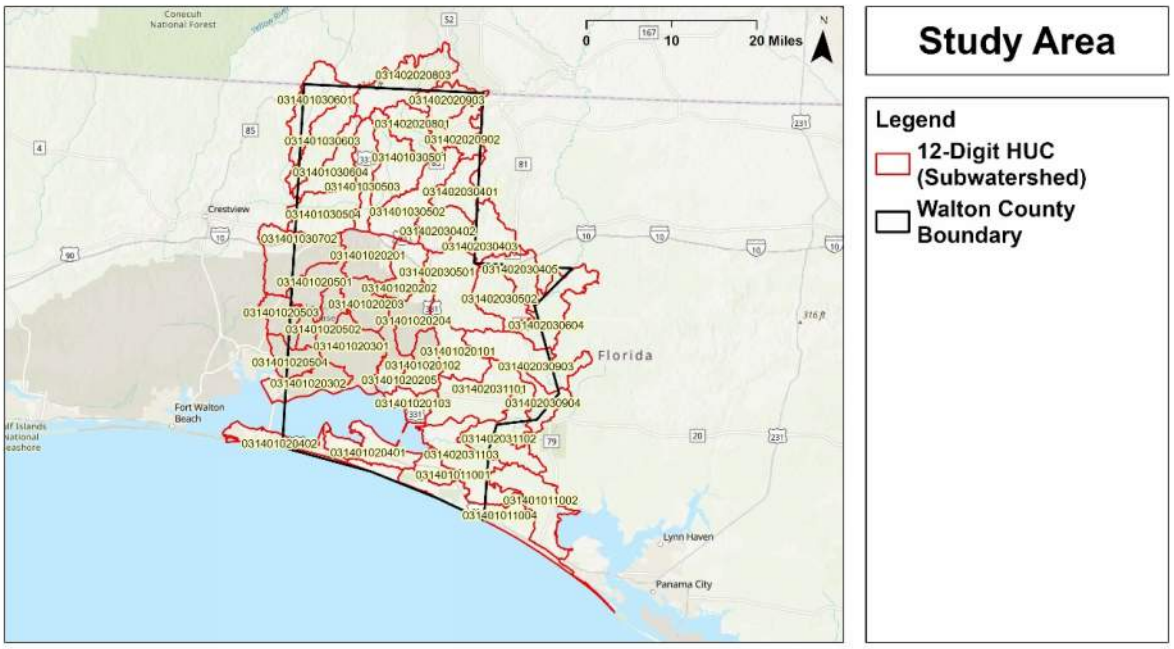

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

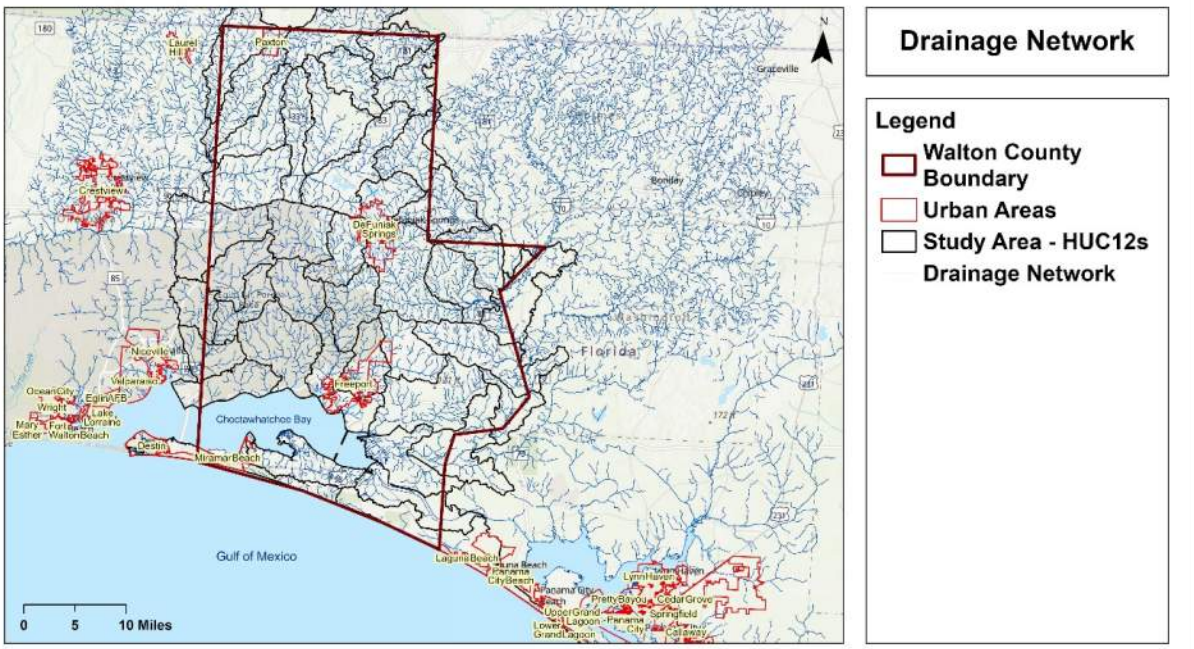

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

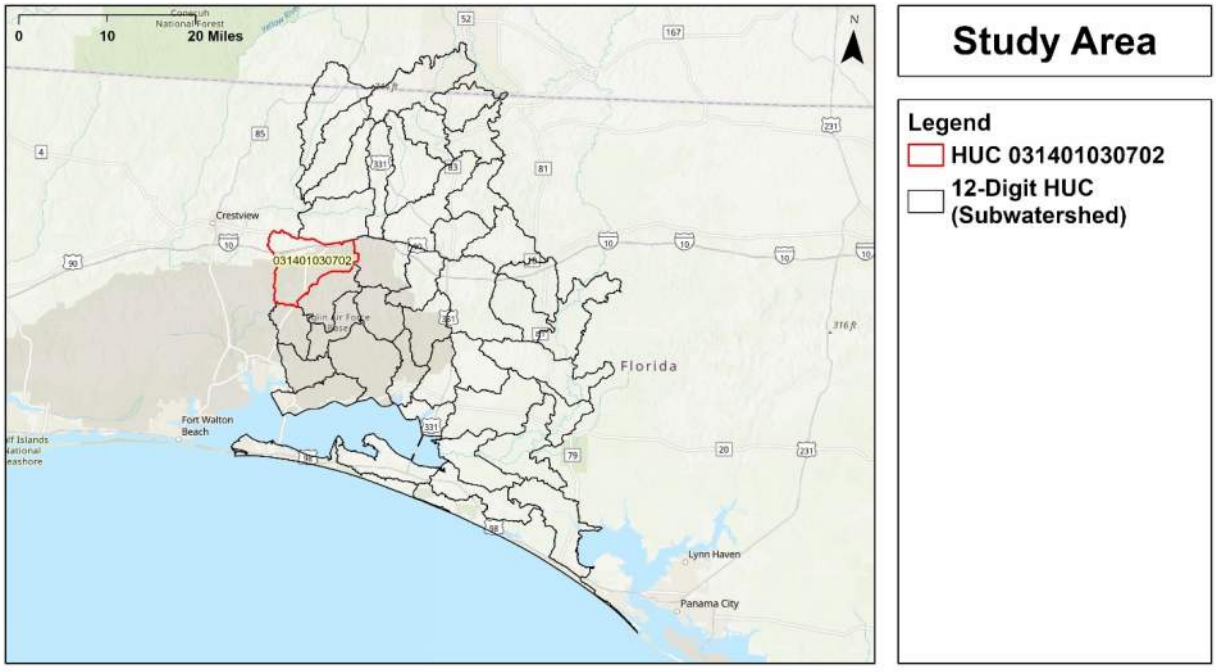

Figure 3. HUC 031401030702 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state,

with a height of 345 feet in its northern end. With a population of 75,305 residents according to the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife

management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

(Source Data: FEMA)

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed (2023 Florida Geographic Data Library (FGDL))

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.

- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

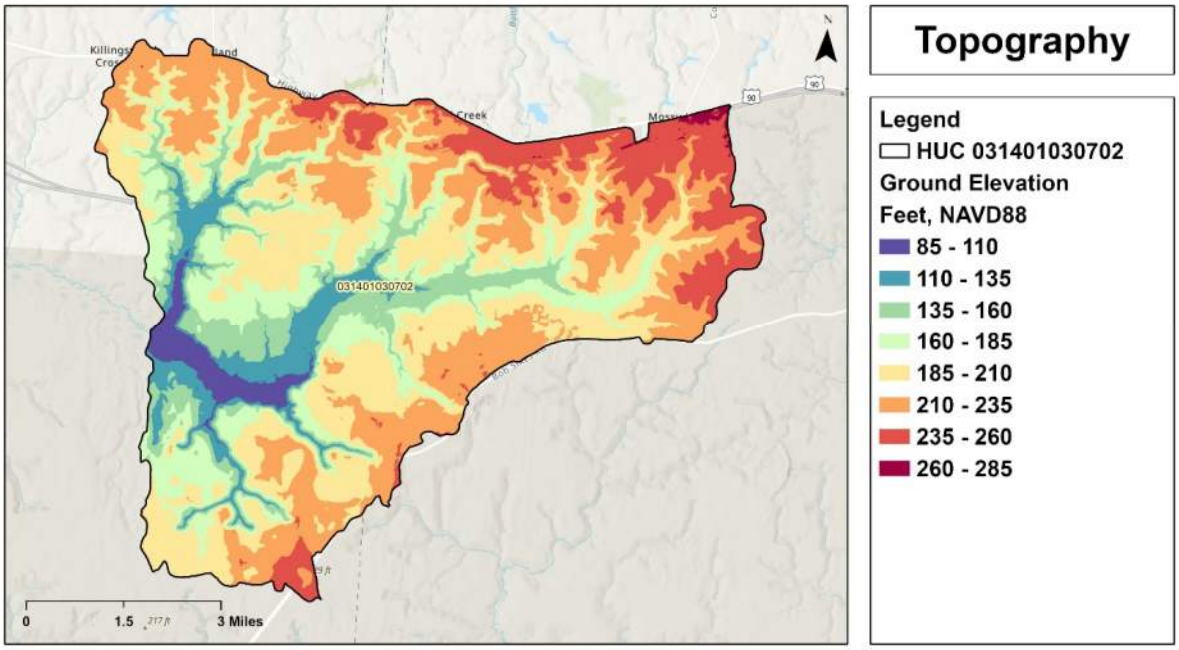

Figure 4. Topographic map of the HUC 031401030702 sub-watershed, processed by FAU.

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031401030702 sub-watershed is shown in **Error! Reference source not found.**.

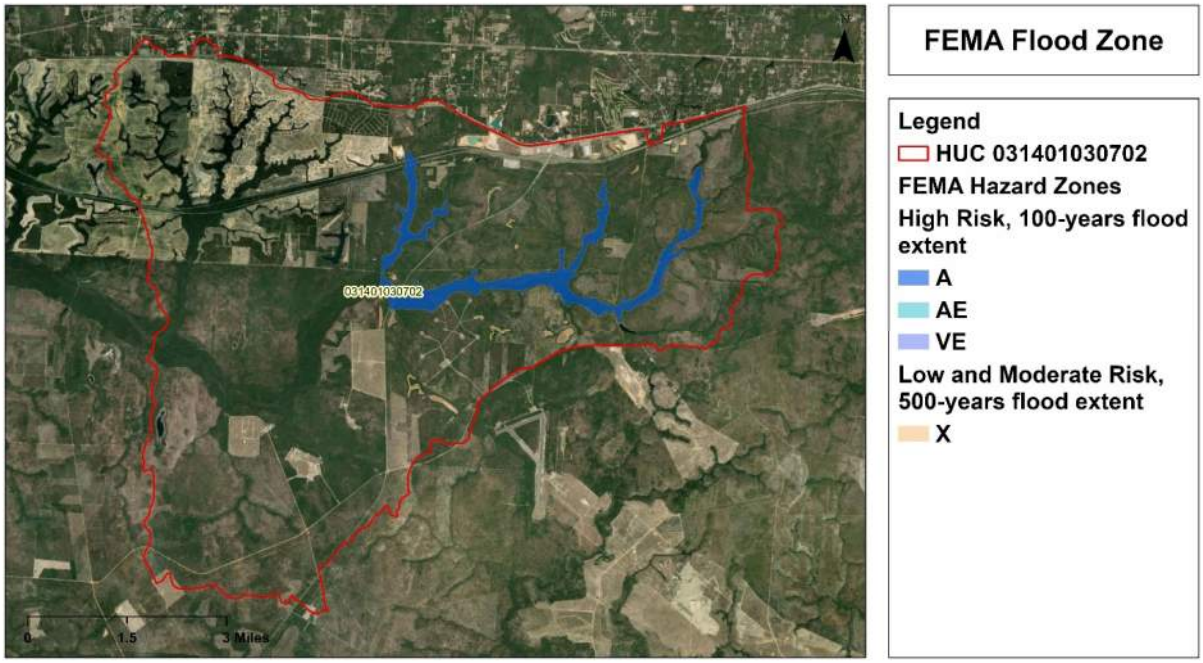

Figure 5. FEMA Flood Zone map (2020) for HUC 031401030702 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031401030702 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including

various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

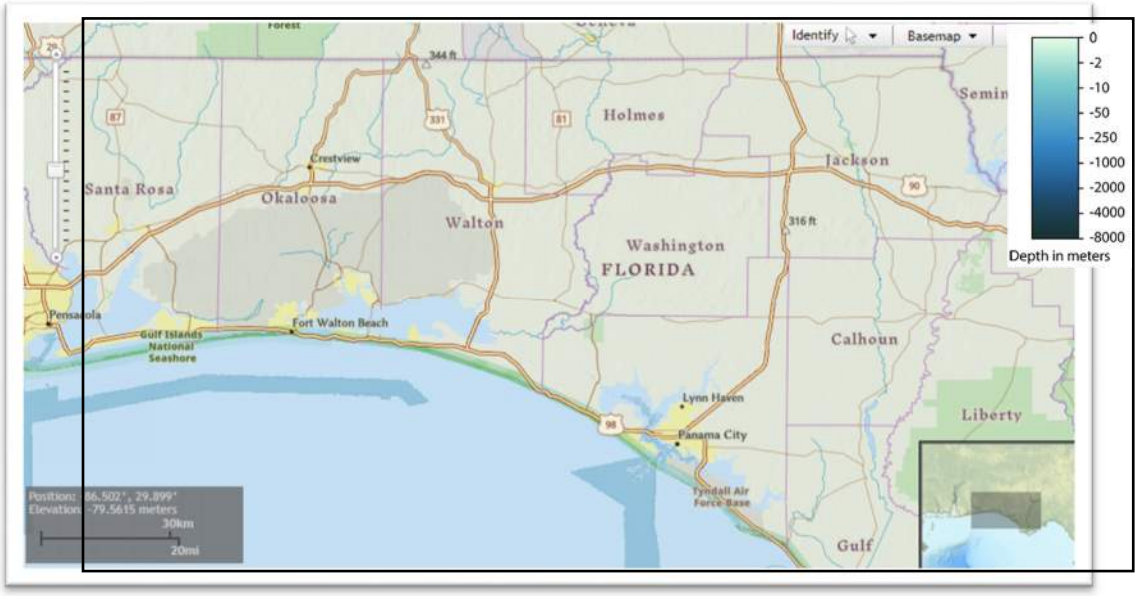

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

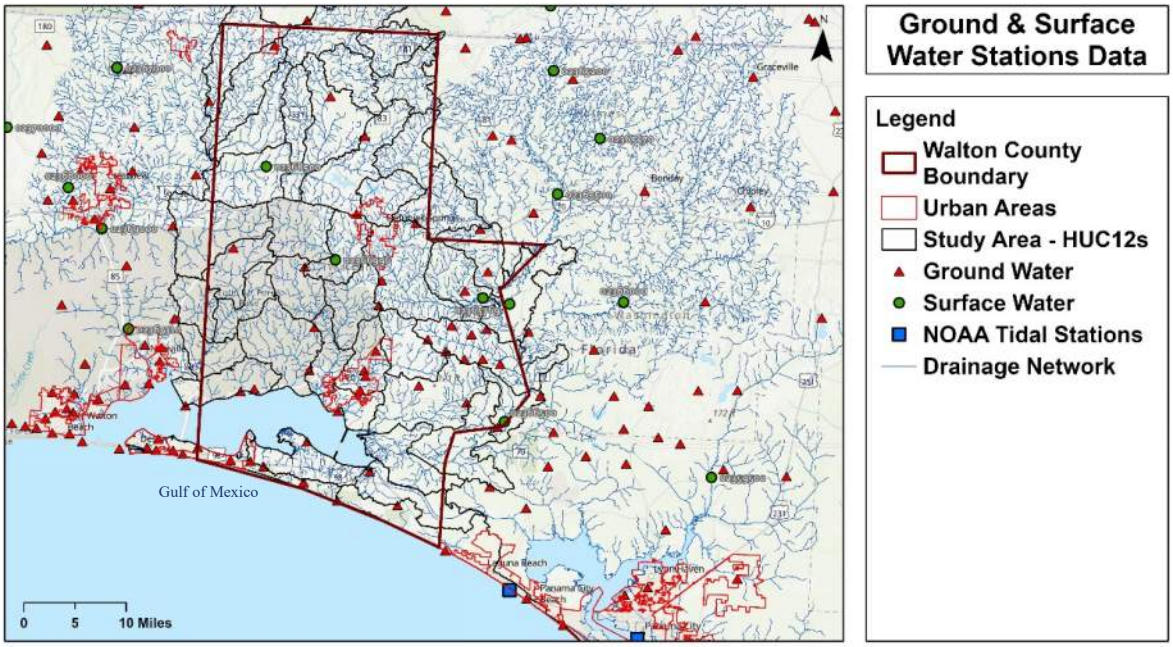

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031401030702 has no major rivers and canals, but creeks and branches, include:

- Titi Creek
- Big Fork
- Cawthon Branch

- Cowpen Branch
- Gum Creek
- East Dog Creek
- Deerland Branch
- West Dog Creek
- Bull Creek
- Ramer Creek
- Deserter Creek
- Wildcat Branch
- Indigo Branch
- Horseshoe Branch
- Wise Creek
- Hog Creek
- Gum Creek

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031401030702, which is USGS 02368500 Shoal River.

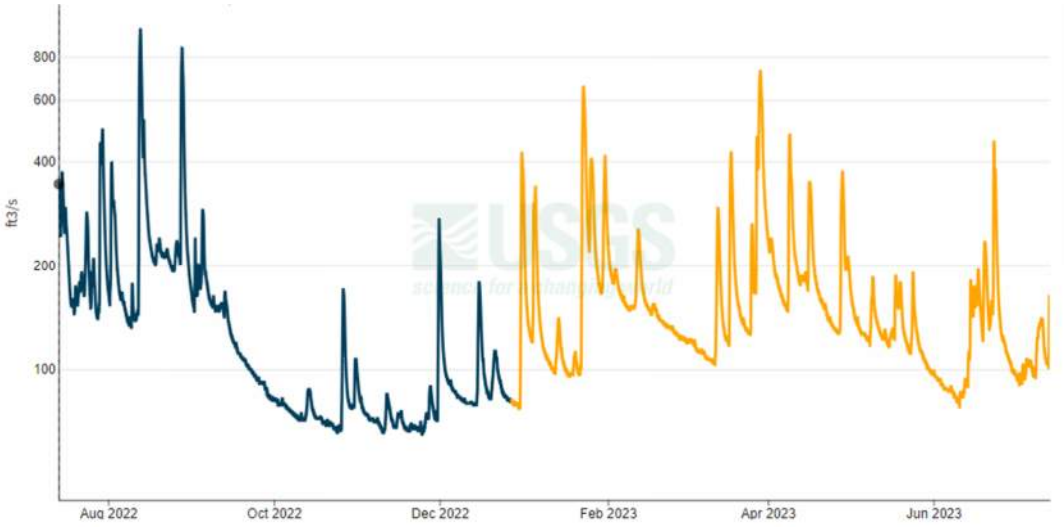

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99^{th}- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98^{th} - 100^{th} percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031401030702 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031401030702 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

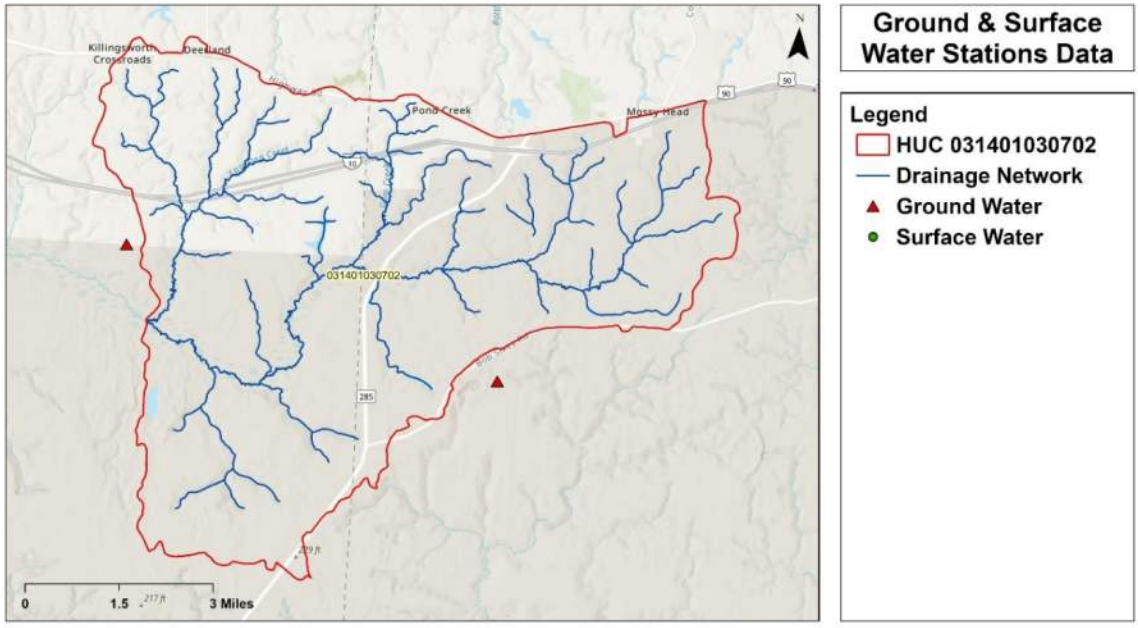

Figure 9. Ground and Surface Water Stations in the HUC 031401030702 sub-watershed, processed by FAU.

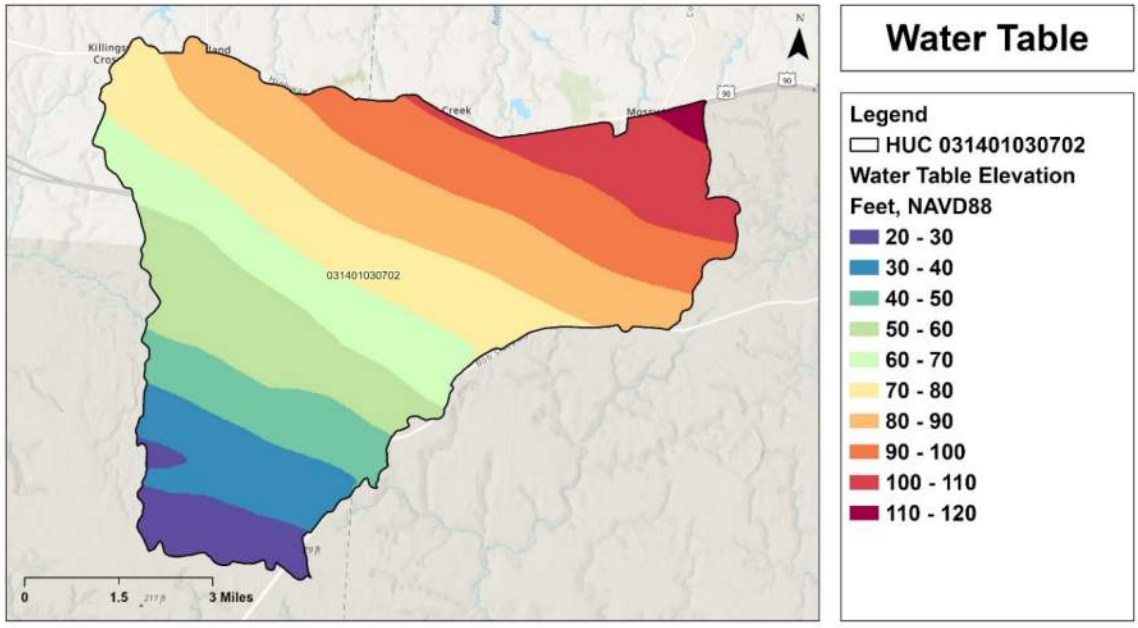

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031401030702 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the average precipitation over Walton County for every month of the year between 2011 and 2023.

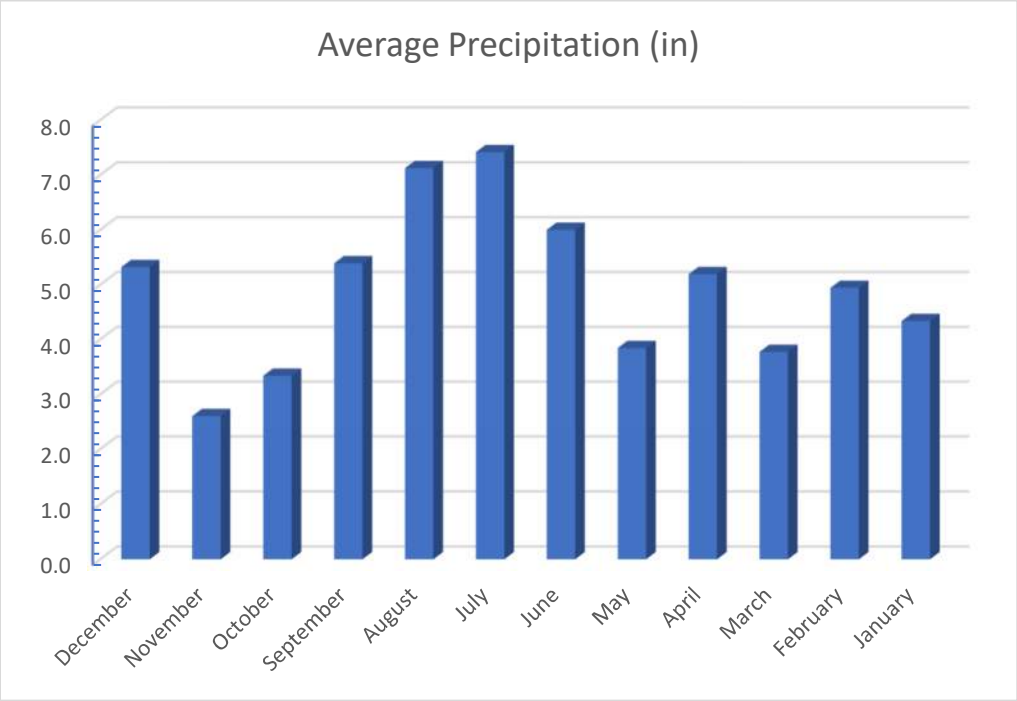

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows

the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

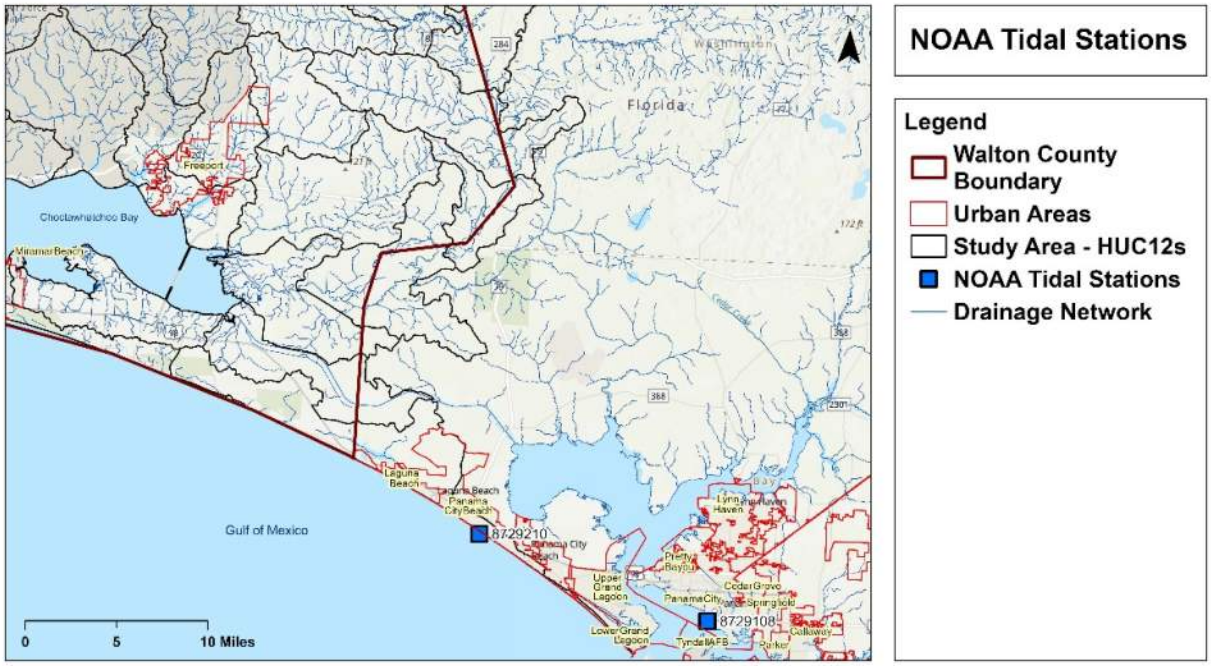

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

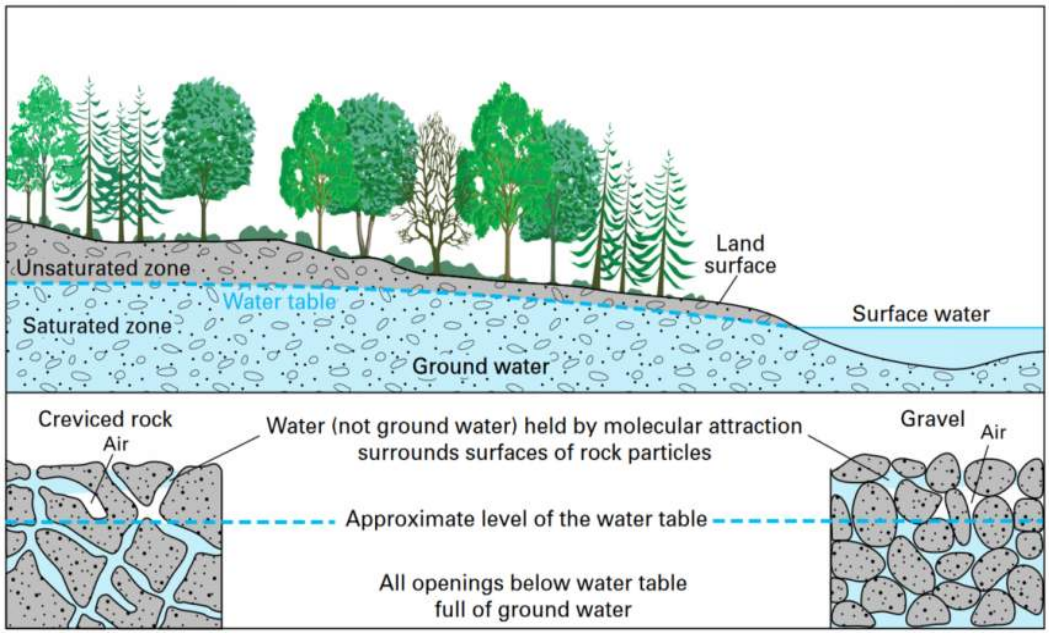

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

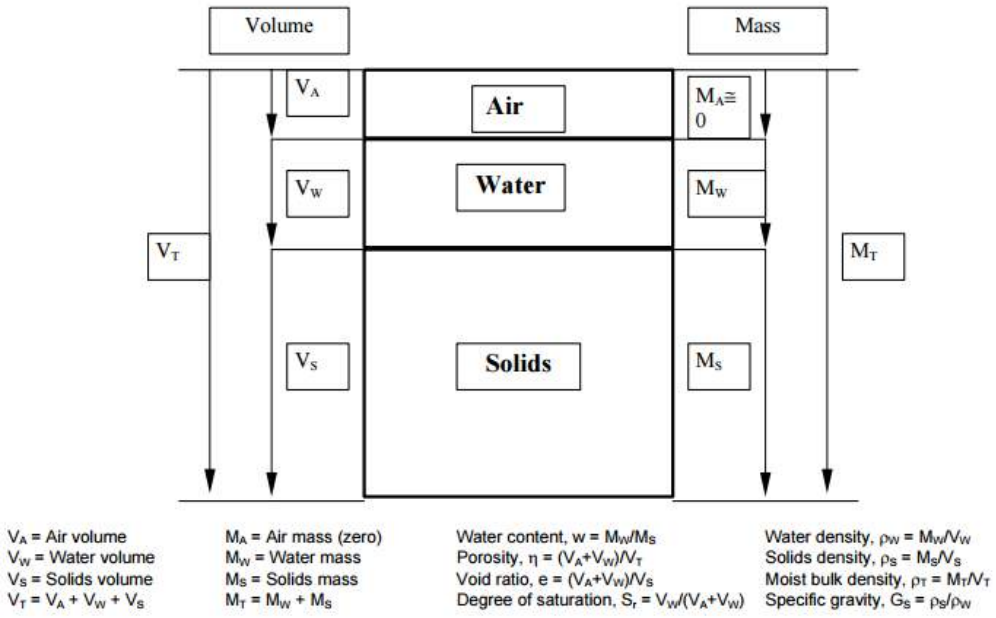

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

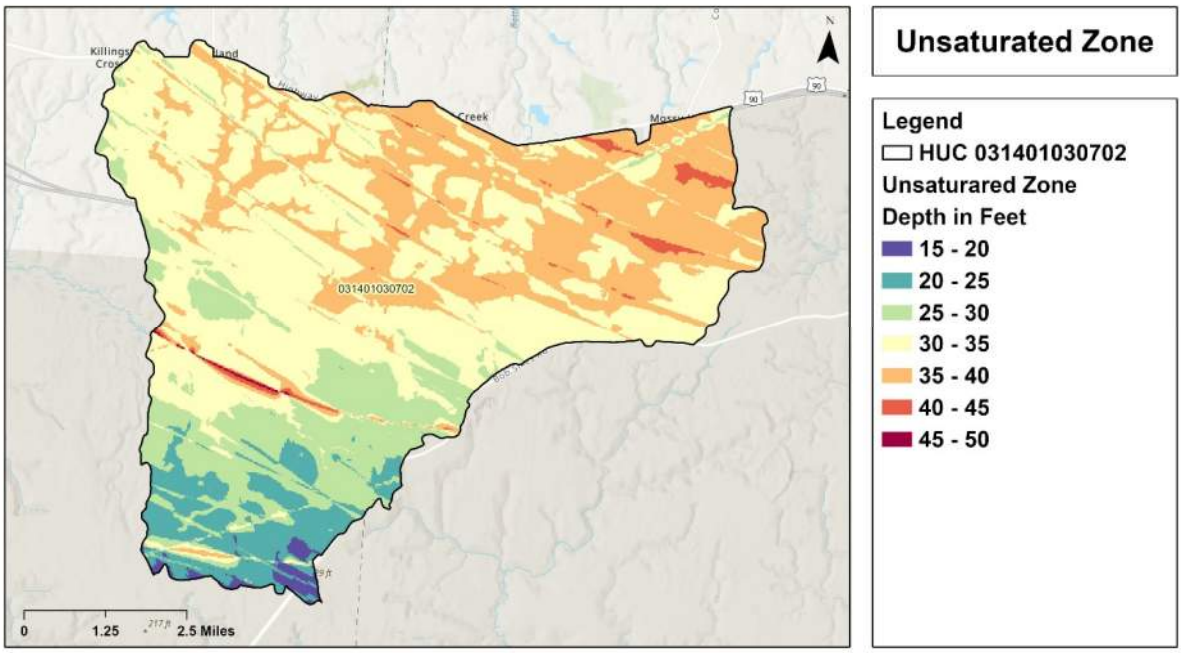

Figure 15. Unsaturated zone map for HUC 031401030702, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. Much of the basin has limited soil storage capacity, ranging between 20 to 40 inches of capacity left.

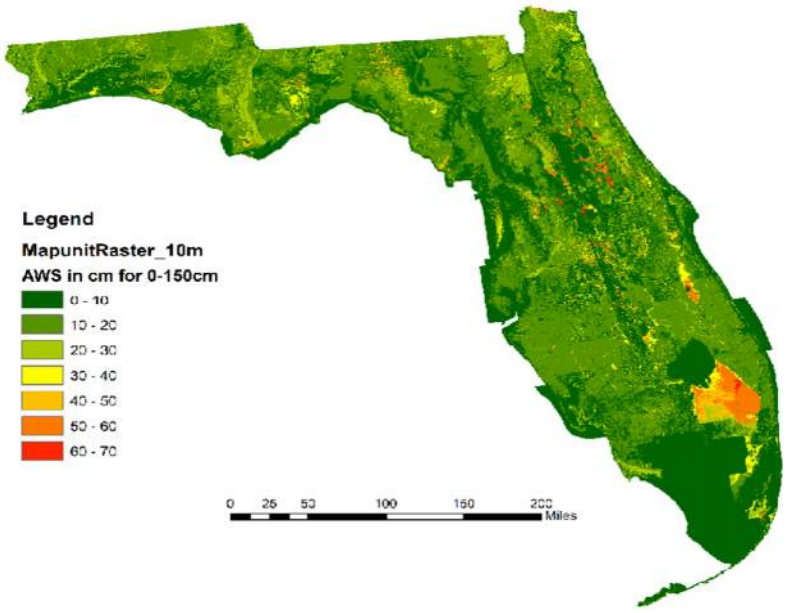

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

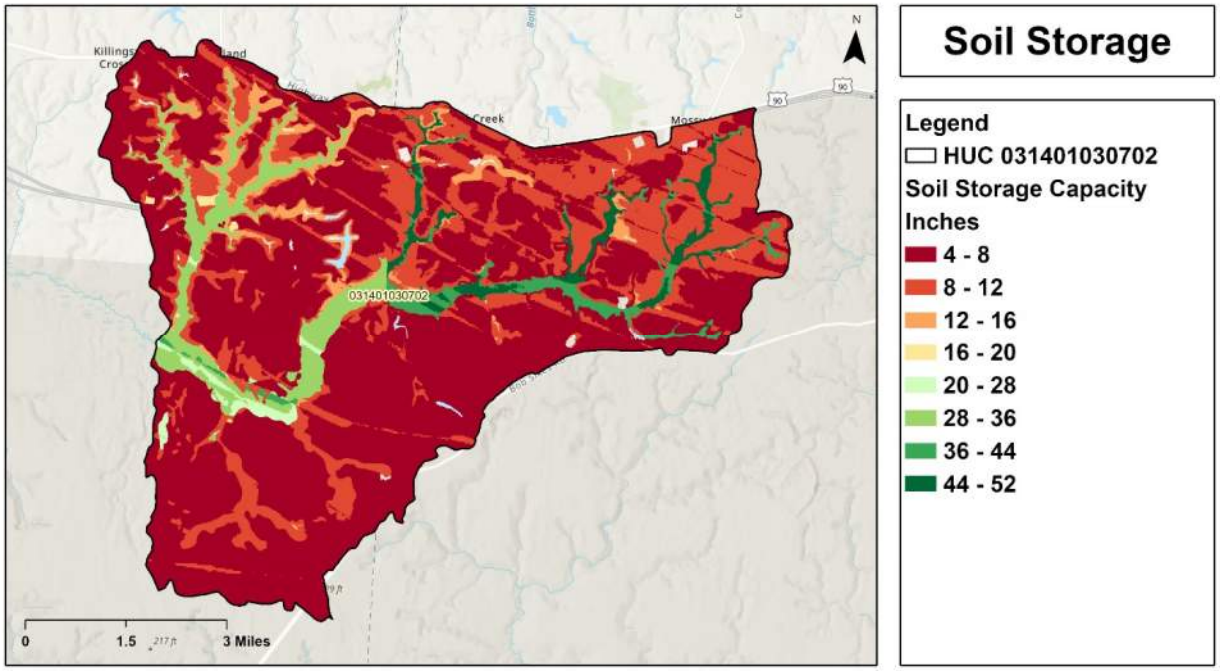

Figure 17. Water storage capacity of soil for the HUC 031401030702 (inches), processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

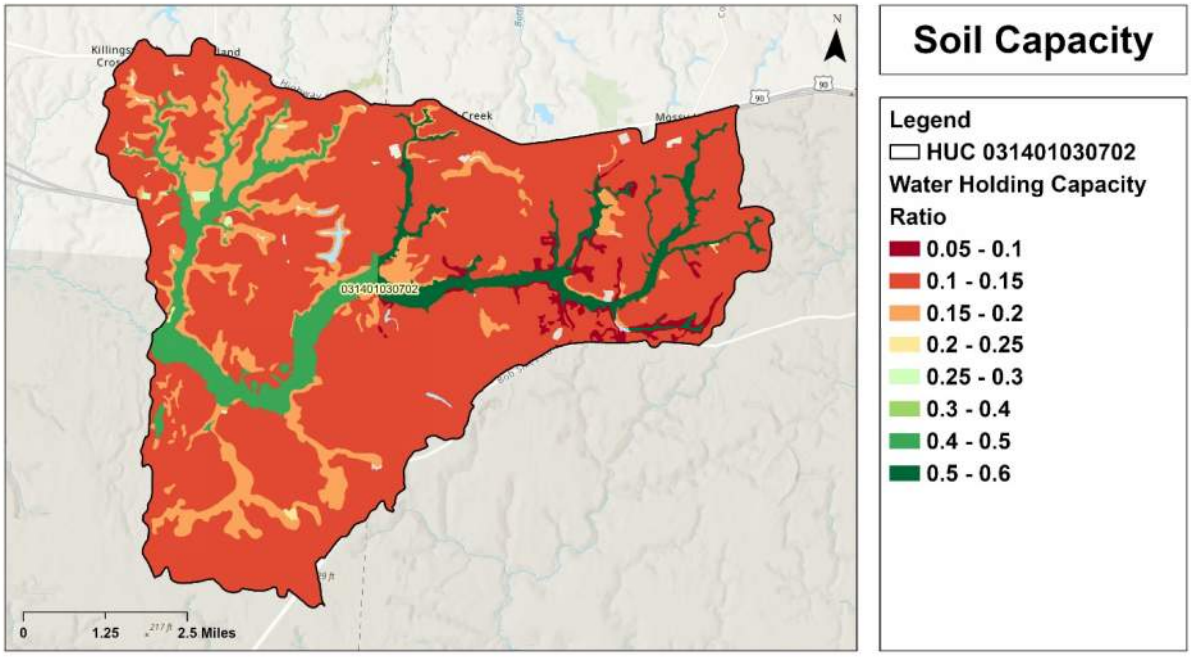

Figure 18: Water Holding Capacity (ratio) for the HUC 031401030702, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

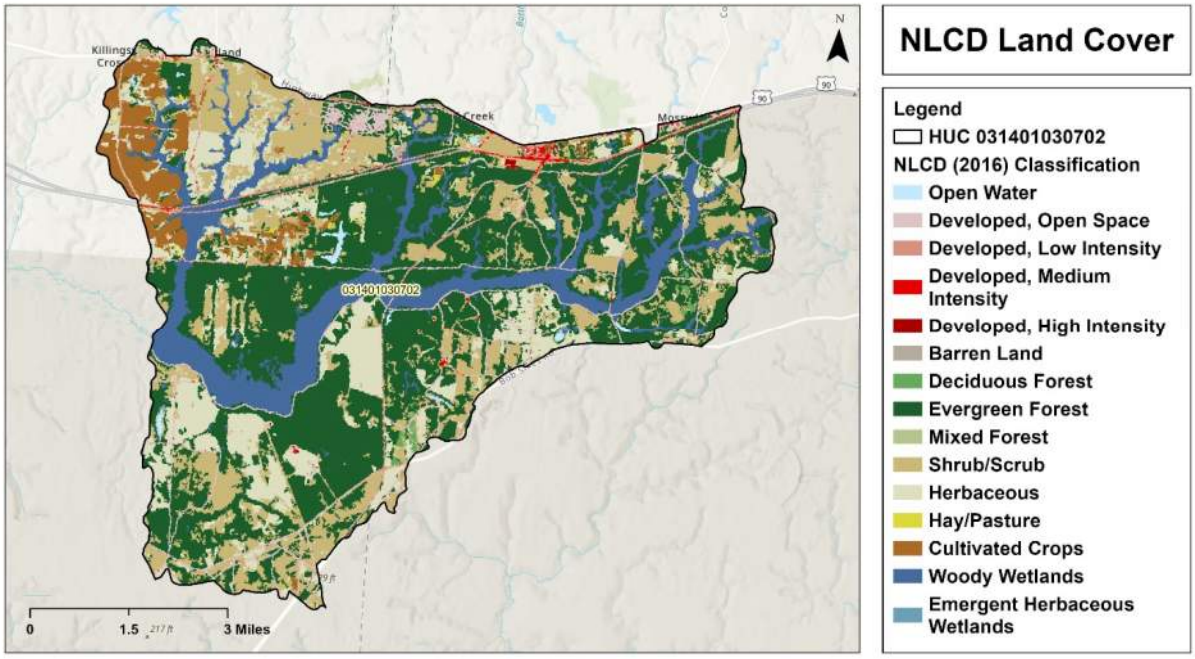

Figure 19. Land use in the HUC 031401030702 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps were used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

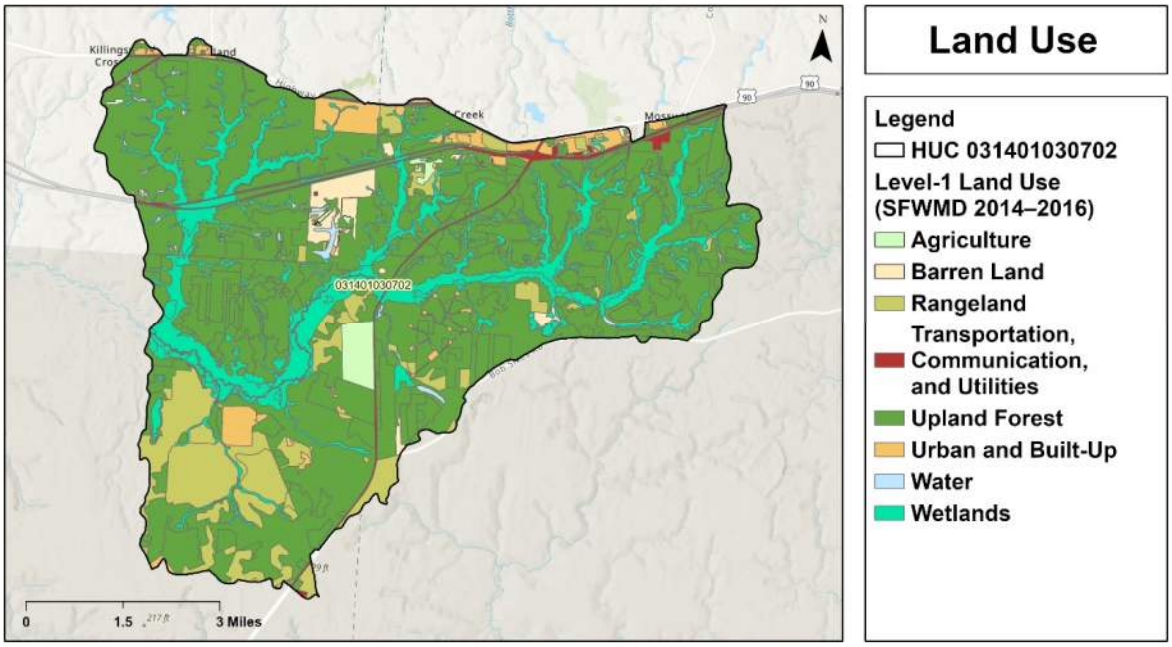

Figure 20. Land use in the HUC 031401030702 processed by FAU (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031401030702 sub-watershed, the predominant land cover is upland forest, accounting for 59.51% of the area. Rangeland comes in second at 14.56%, followed by wetlands at 11.50%, and Transportation, Communication, and Utilities at 7.85%. Developed land constitutes a minor portion, with only 3.15% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031401030702 subwatershed.

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	384.80	0.95%
Barren Land	528.28	1.31%
Rangeland	5892.16	14.56%
Transportation, Communication, and Utilities	3174.66	7.85%
Upland Forest	24077.91	59.51%
Urban and Built-Up	1275.42	3.15%
Water	476.71	1.18%
Wetlands	4653.09	11.50%
Grand Total:	**40463.03**	**100.00%**

(Source Data: 2023 Florida Geographic Data Library (FGDL) database))

Table 4. Roughness and CN Values for Each Land Use Code.

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). Figure 21 shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

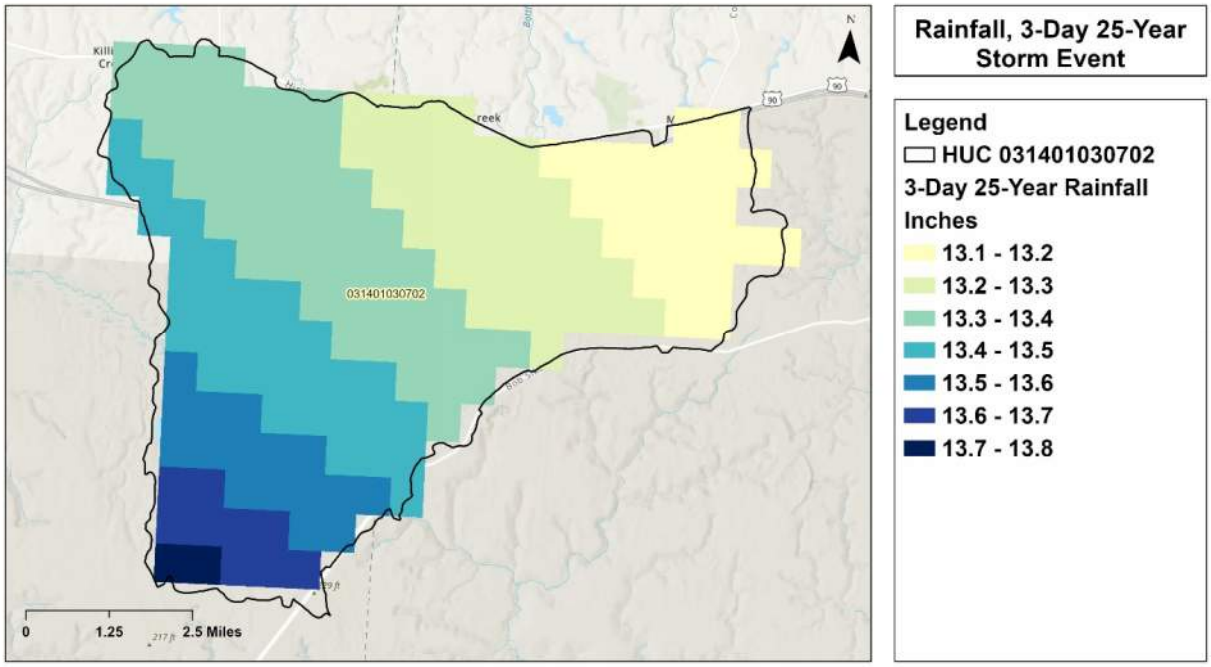

Figure 21. Rainfall distribution map across HUC 031401030702 sub-watershed, for 3-day 25-year storm event, processed by FAU.

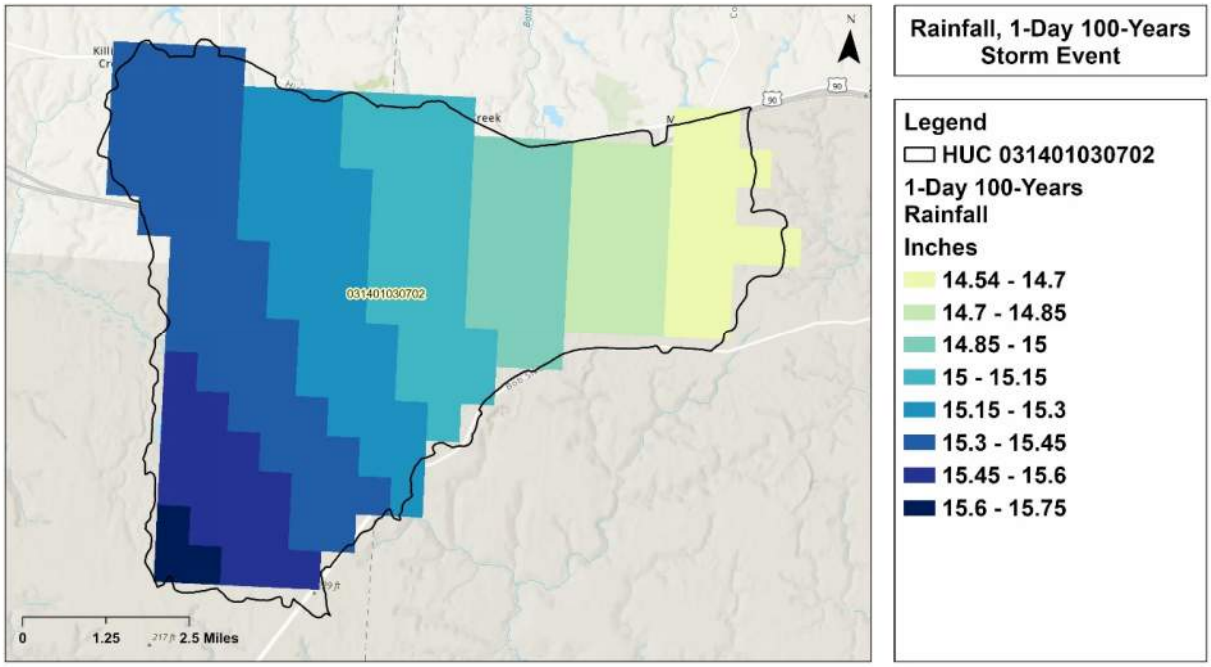

Figure 22. Rainfall distribution map across HUC 031401030702 sub-watershed, for 1-day 100-year storm event, processed by FAU.

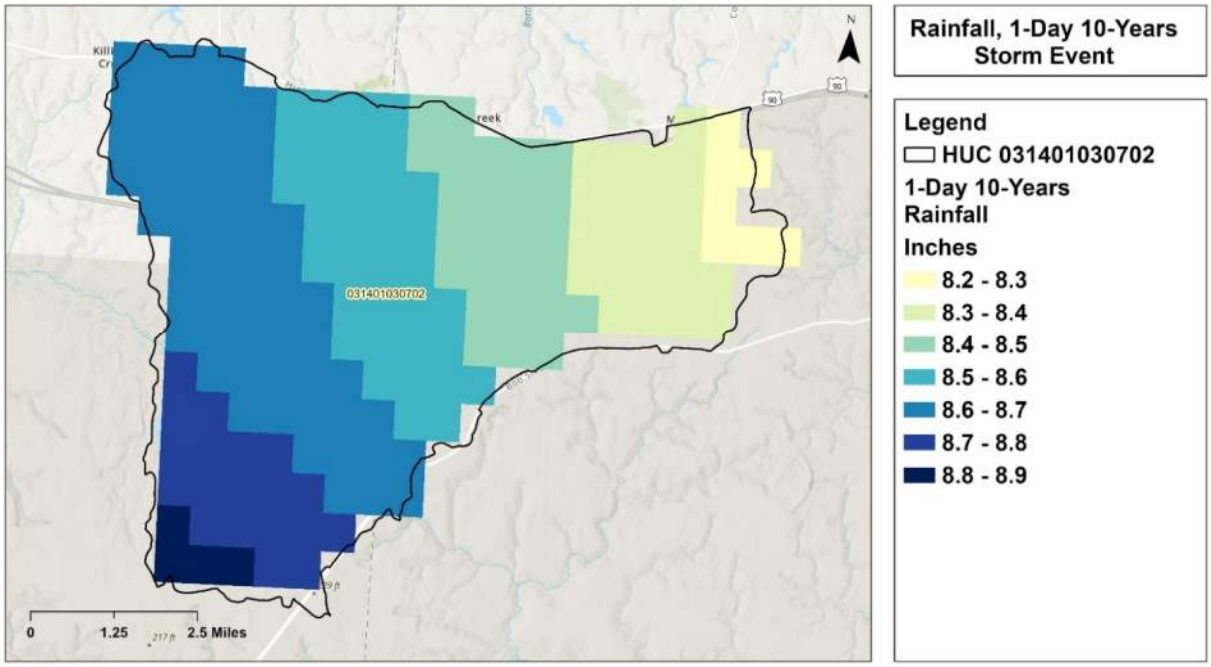

Figure 23. Rainfall distribution map across HUC 031401030702 sub-watershed, for 1-day 10-year storm event, processed by FAU.

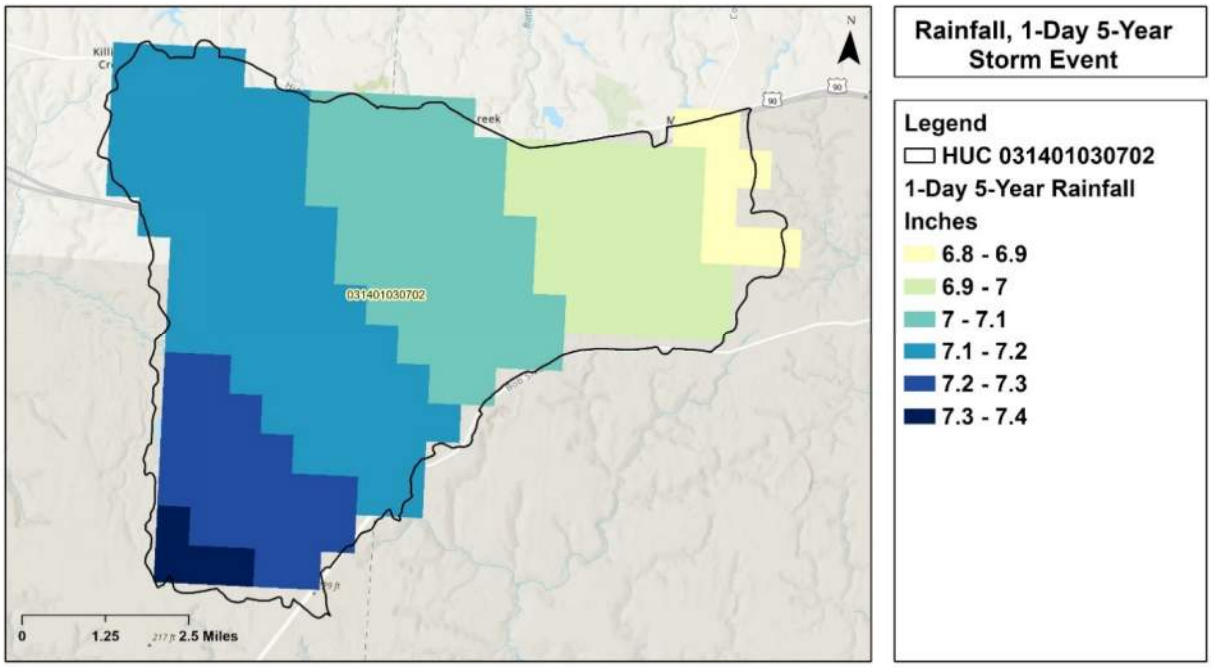

Figure 24. Rainfall distribution map across HUC 031401030702 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

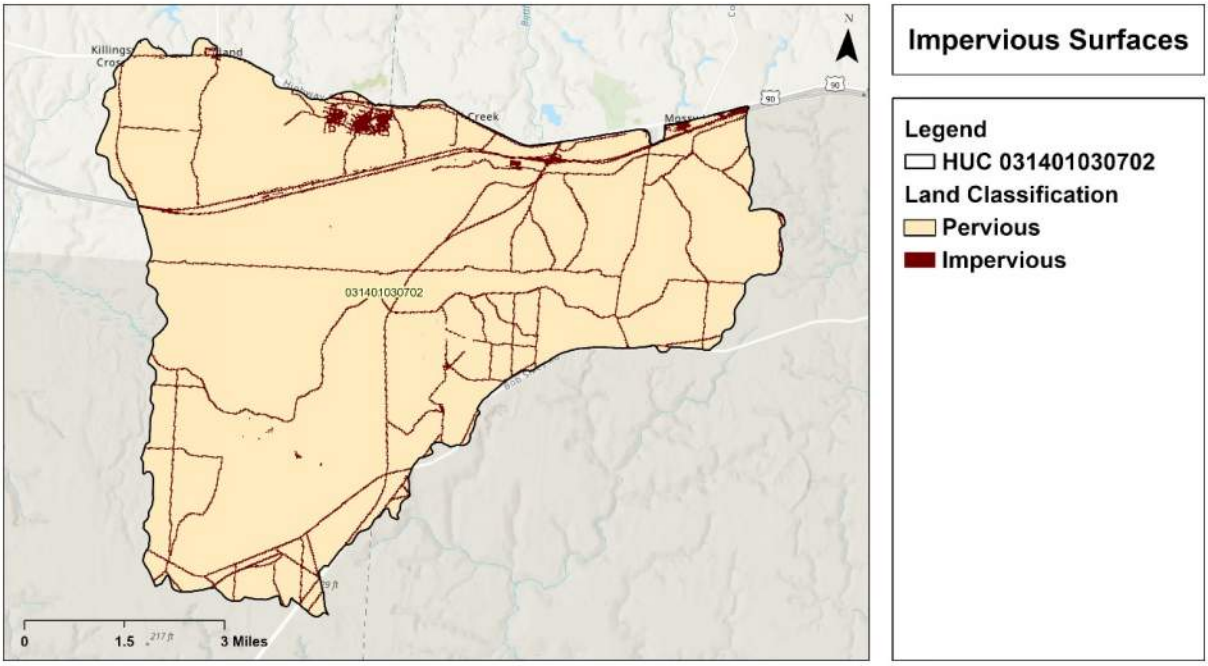

Figure 25. Impervious area map for the HUC 031401030702 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

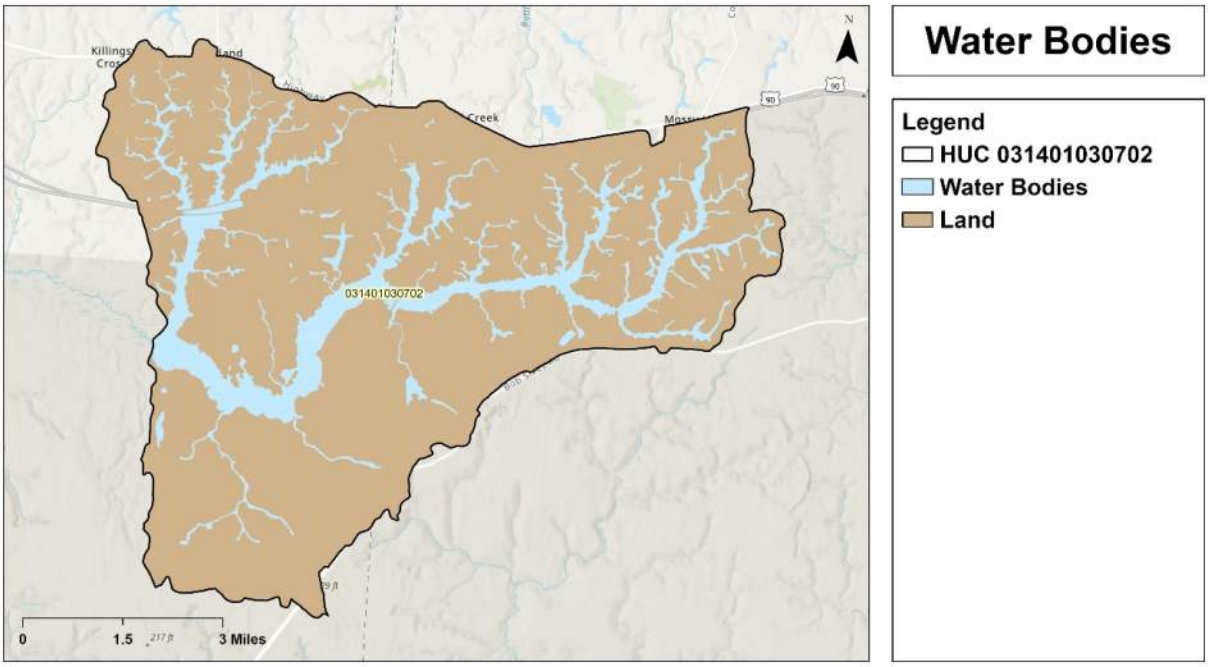

Figure 26. Water bodies map for the HUC 031401030702 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County
Area in square miles	7.02	18.94	13.95	4.01	17,021	68,722	1,038.29
Population (Census 2020)	8,002	5,861	5,919	556	2,878	20,567	75,305
Total Households	4,334	2,206	2,509	316	1,318	8,275	30,182
Median Household Income	$75,347	$75,637	$53,984	$41.750	$127,148	$94,648	$68,111
Median Age	56.3 years	41.4 years	37.1 years	50.6 years	52.4 years	43.20 years	45.0 years
White	7,688	2,086	4,021	482	2,638	17,268	89.8%

Another Race	14	52	105	5	22	925	0.2%
Two or More Races	674	185	299	38			2.7%
Hispanic or Latino (Regardless of Race)	434	156	127	66	105	1,988	7.1%

(Source: US Census Bureau 2020, and Zip-codes.com)

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.

- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

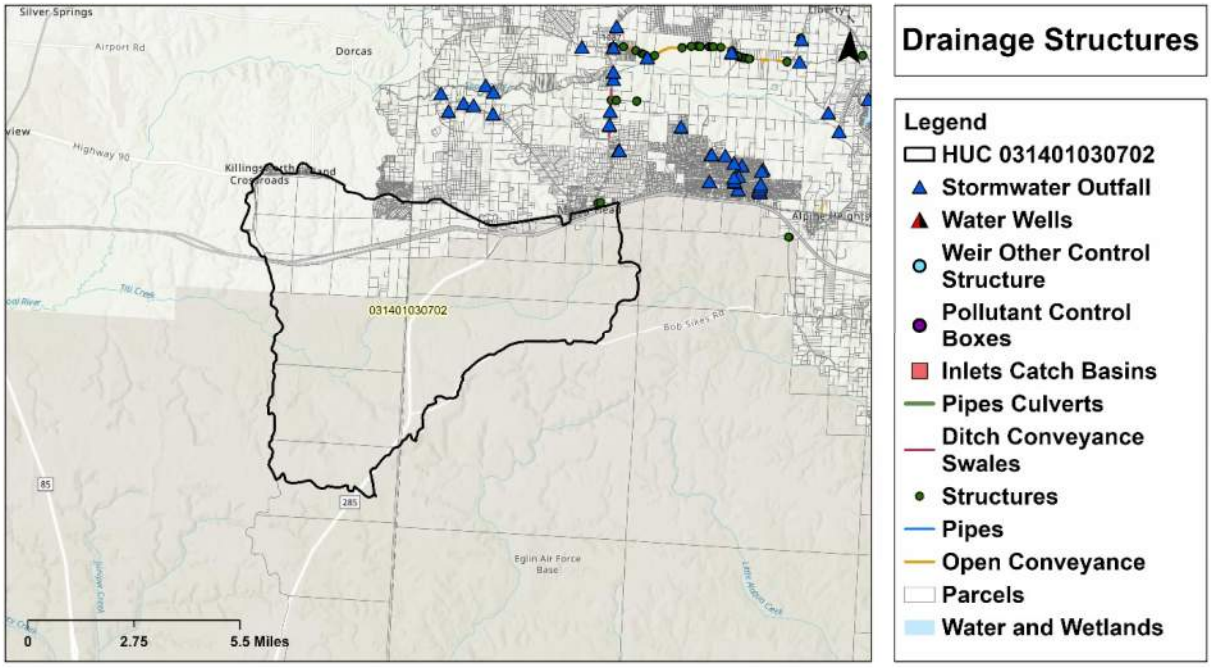

Figure 27. Stormwater Infrastructure for the HUC 031401030702. Processed by FAU.

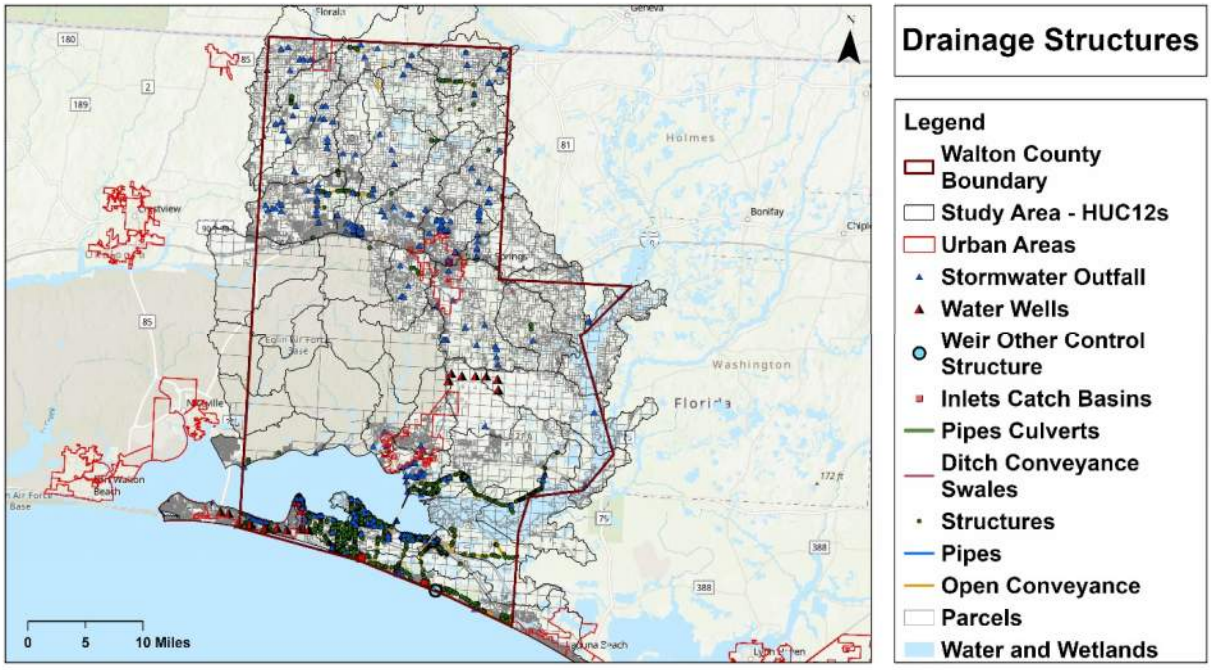

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020).

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1, analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031401030702 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.3.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

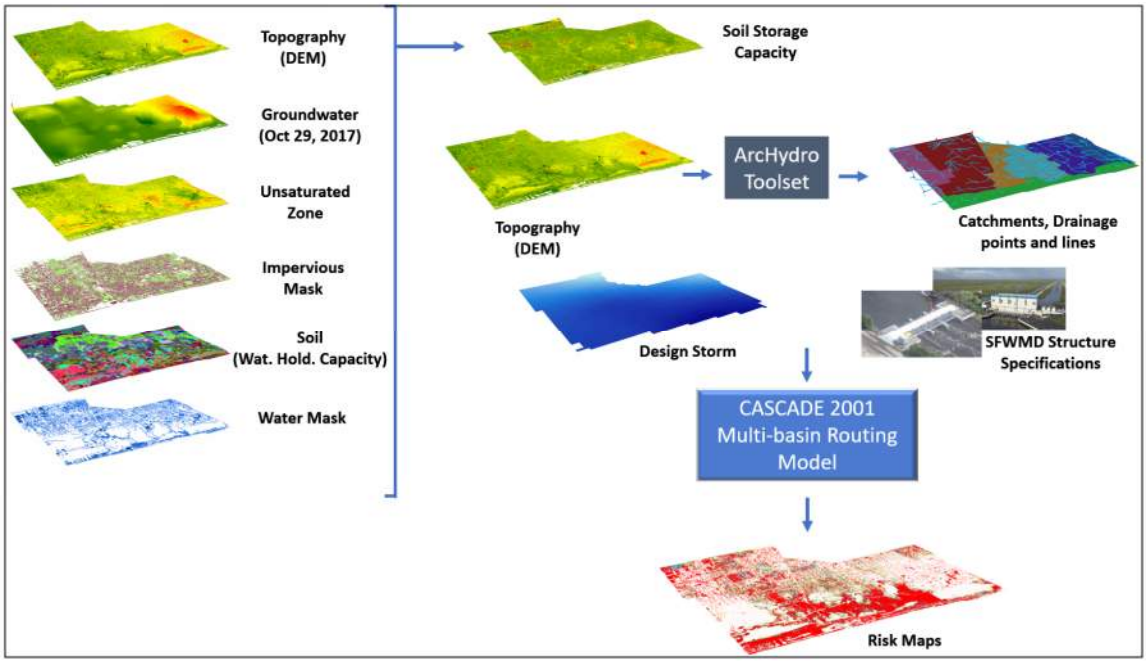

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

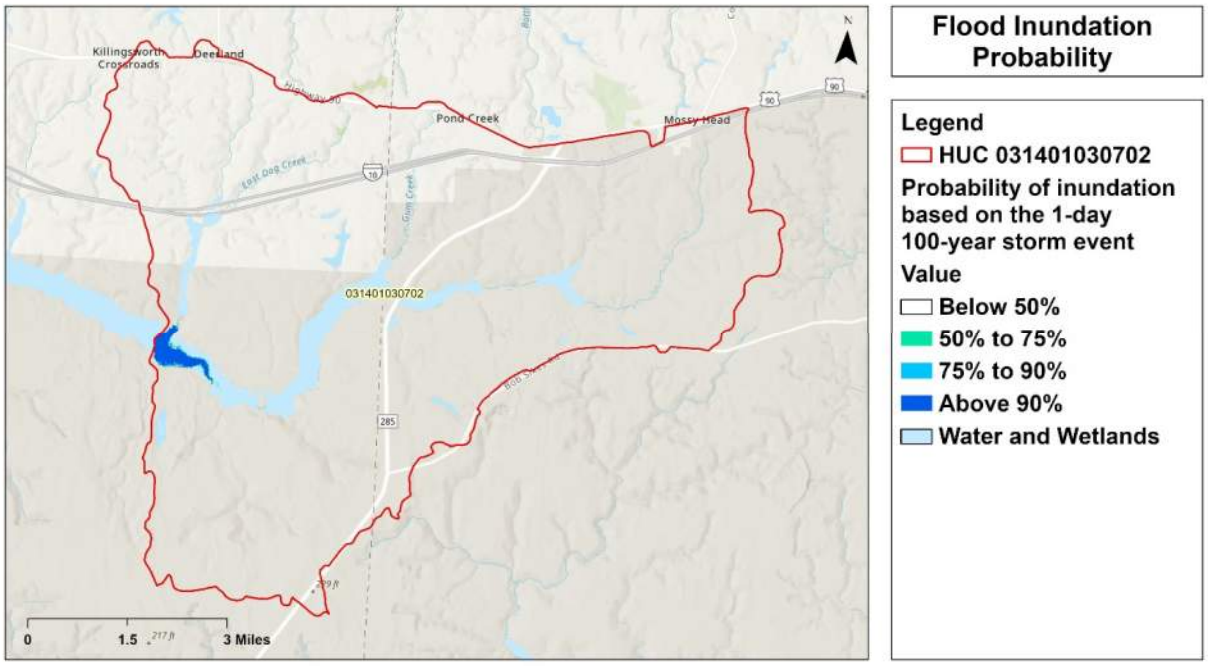

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031401030702, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital

elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 2.4 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the creek entrance to the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 0.5% of the HUC total area or 0.25 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.52% of the HUC's total area, or 0.26 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.44% of the HUC's total area, or 0.22 mi^2,

would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.42% of the HUC's total area, or 0.21 mi², would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031401030702 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	49.01	0.25	99.50%	0.50%
1-day 100-year	49.00	0.26	99.48%	0.52%
1-day 10-year	49.04	0.22	99.56%	0.44%
1-day 5-year	49.05	0.21	99.58%	0.42%

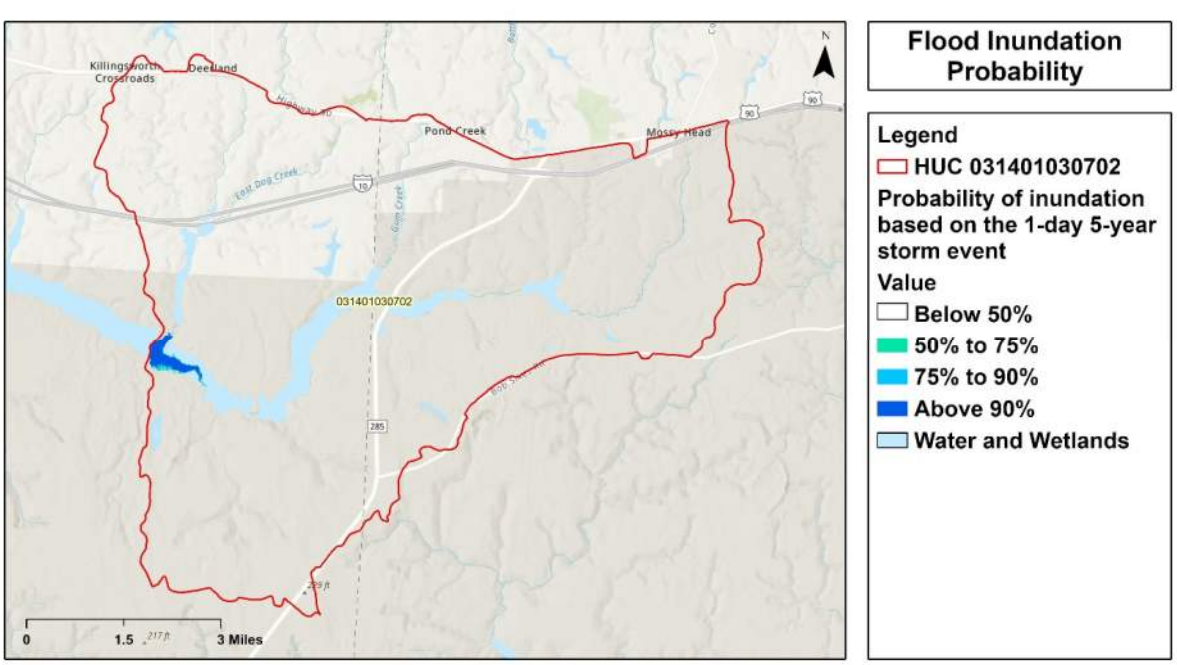

Figure 34. 1-day 5-year storm event for HUC 031401030702 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031401030702 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (**Error! Reference source not found.**) exclusively displays critical facility parcels within the HUC without any flooding. The second map (**Error! Reference source not found.**) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

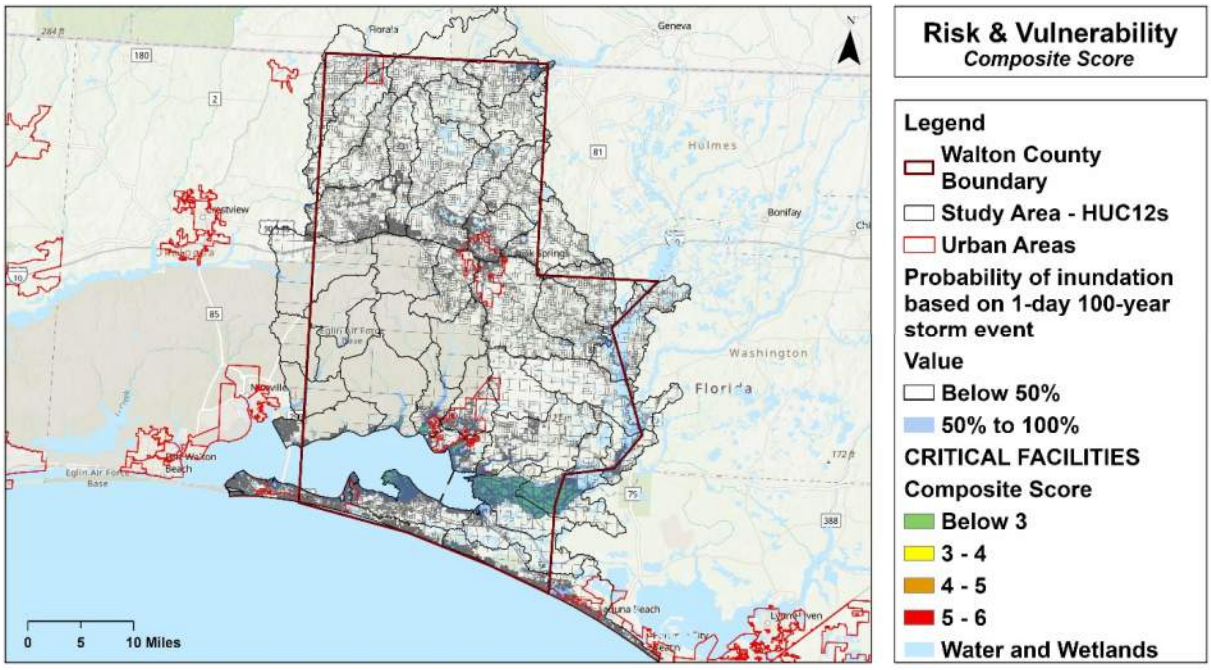

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031401030702. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding.

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031401030702. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031401030702	31522.36
All of the 1-day 100-year storm event inundation	**164.64**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	18.47
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	146.18
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	146.18

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that

have a higher concentration of properties prone to repetitive losses. . **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

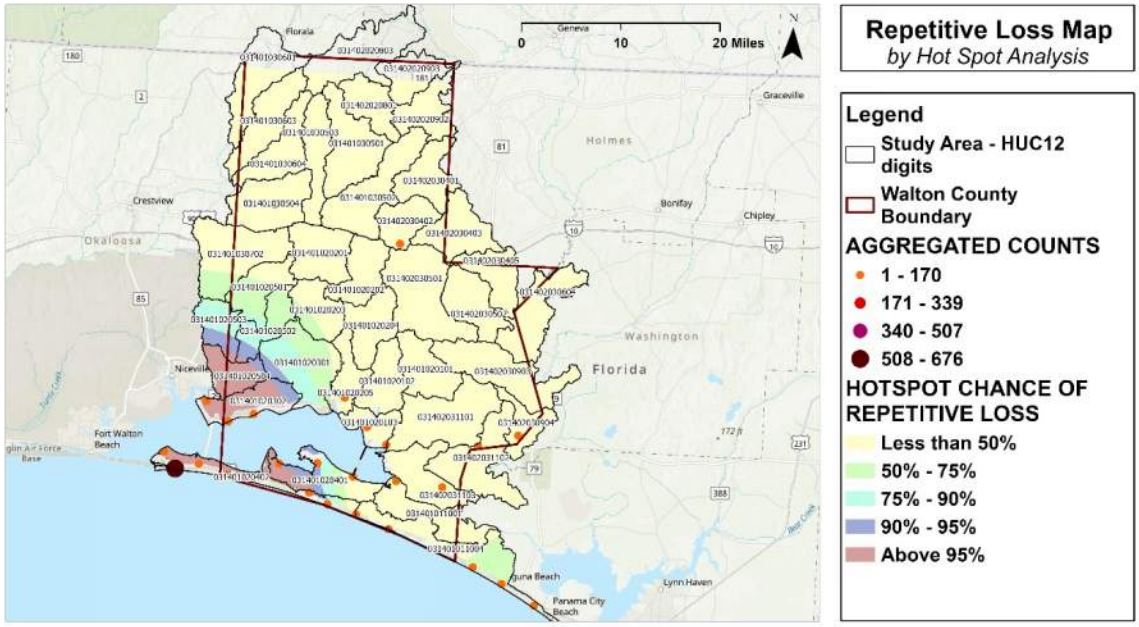

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are some parcels falling within tiers 2 (roads), 3, 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding in the area is minor and not alarming. Consequently, when considering the composite score, it is notable that the results are null, indicating no priority for intervention within the basin.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 (031402020801) is highlighted among all the HUCs to help identify its location. (Figure 3).

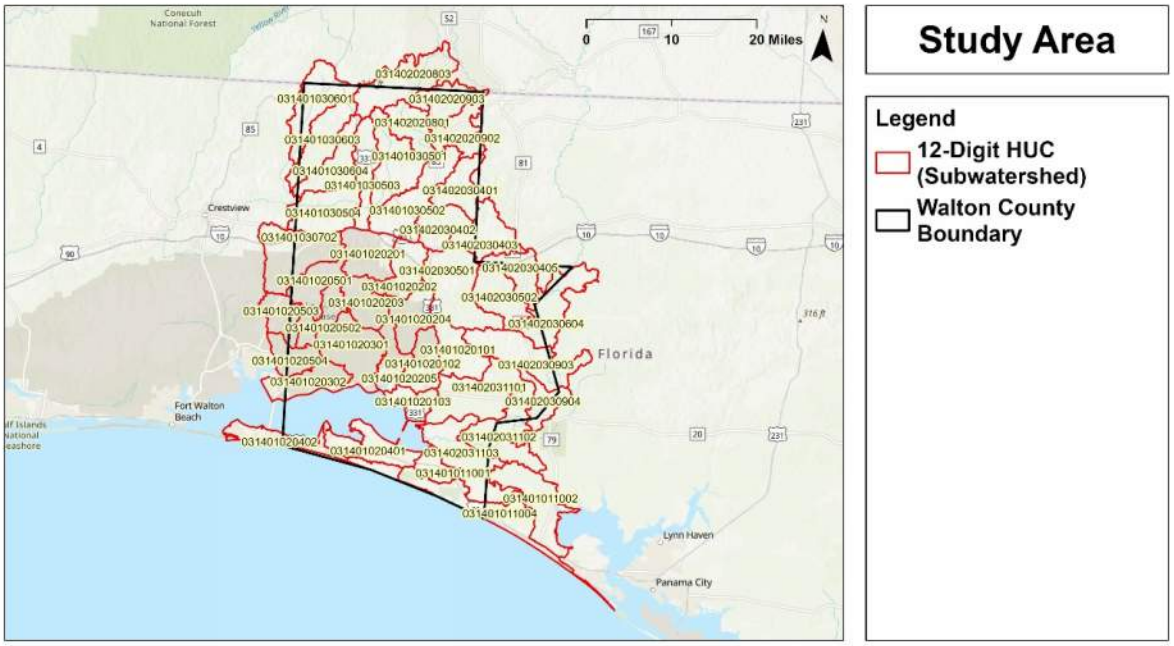

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

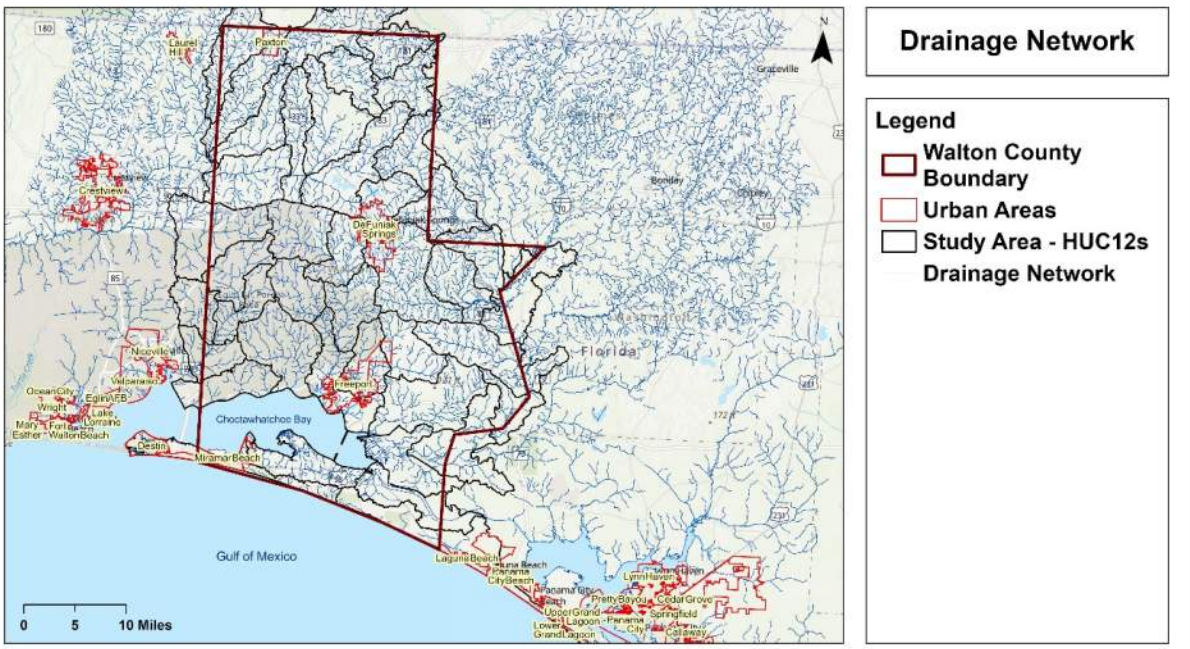

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

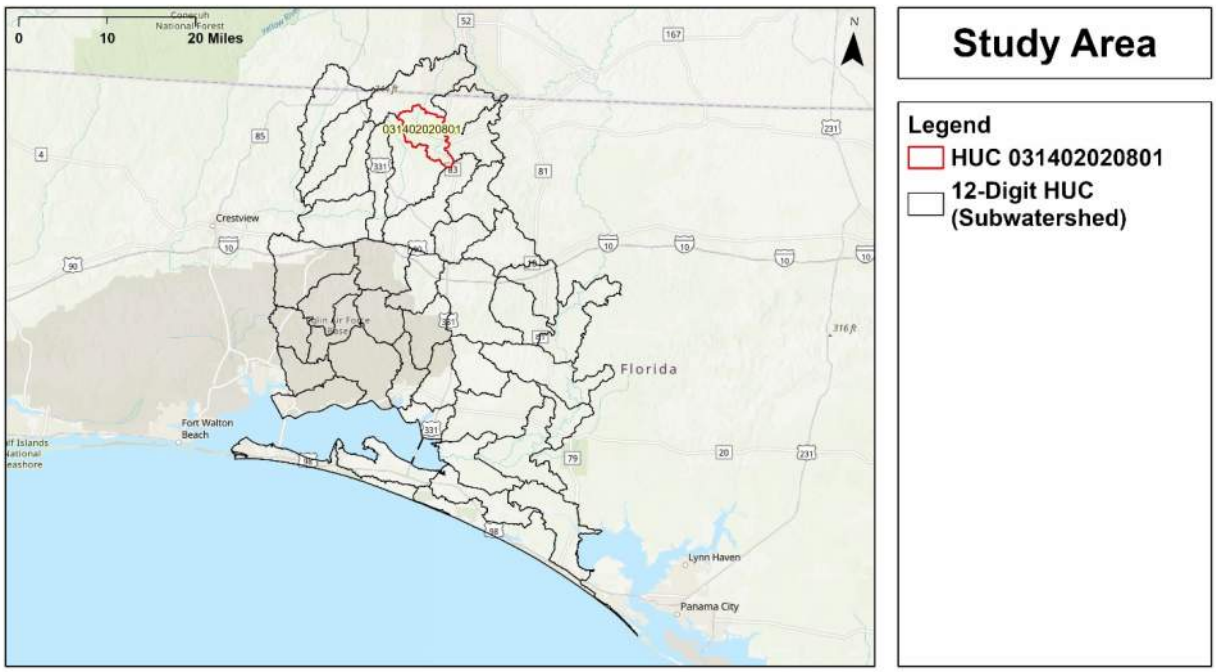

Figure 3. HUC 031402020801 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

(Source Data: NWFWMD, 2017)

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

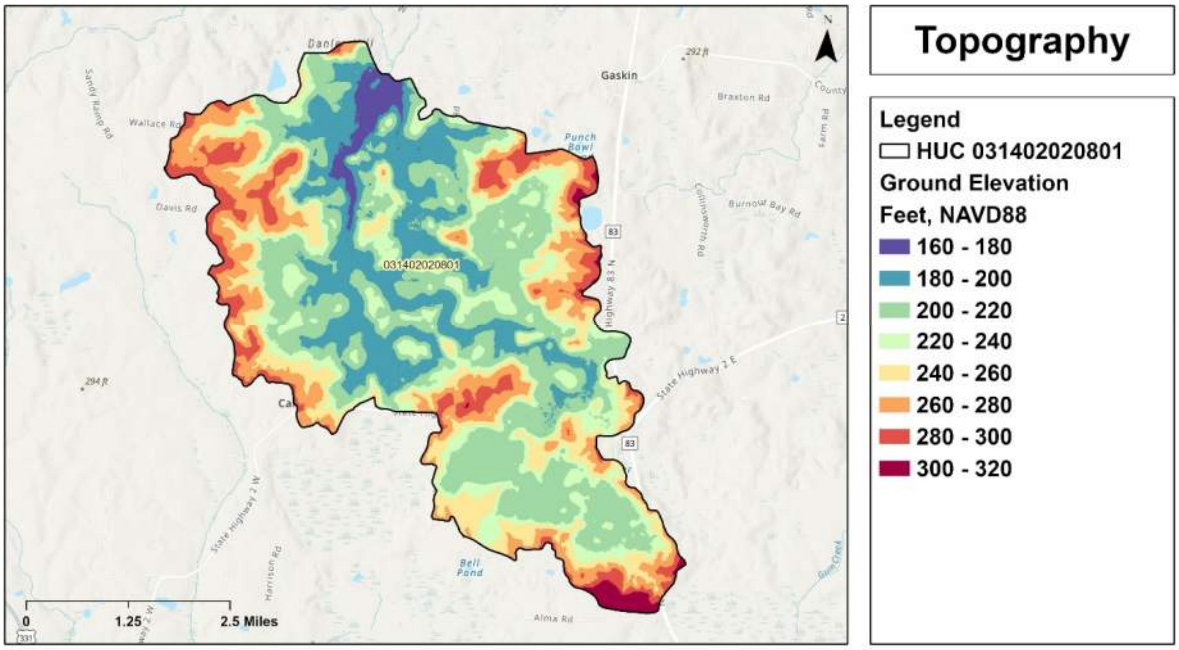

Figure 4. Topographic map of the HUC 031402020801 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology.
Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.
Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031402020801 sub-watershed is shown in **Error! Reference source not found.**..

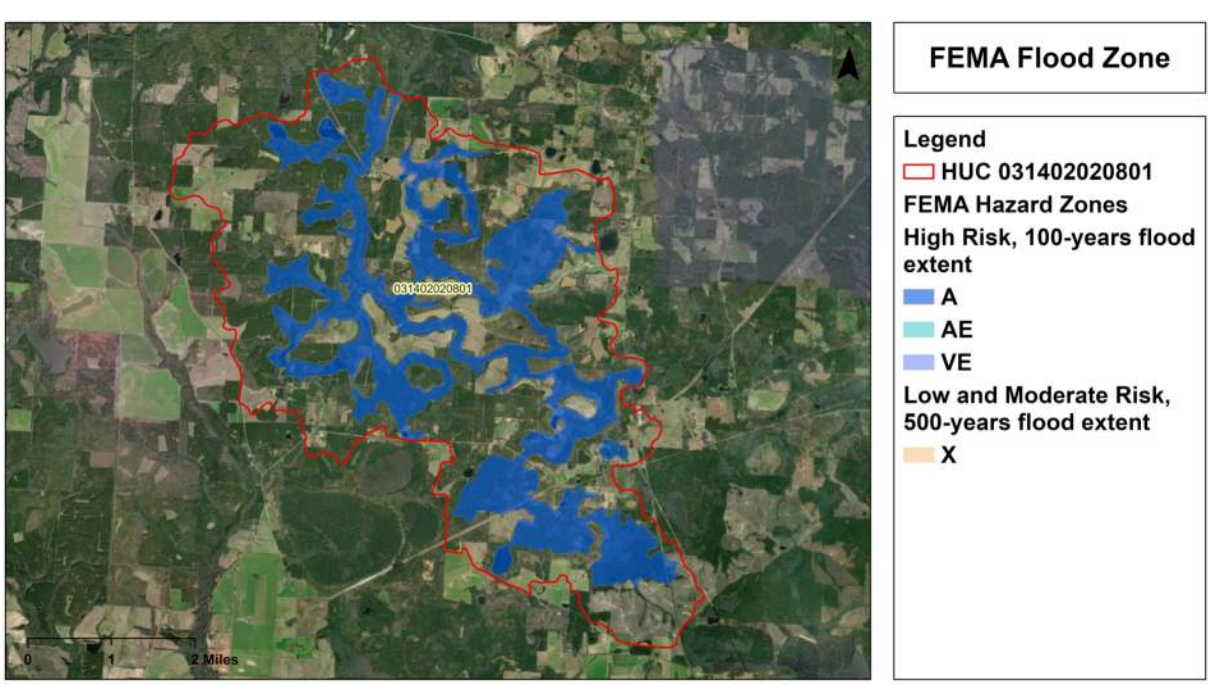

Figure 5. FEMA Flood Zone map (2020) for HUC 031402020801 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031402020801 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

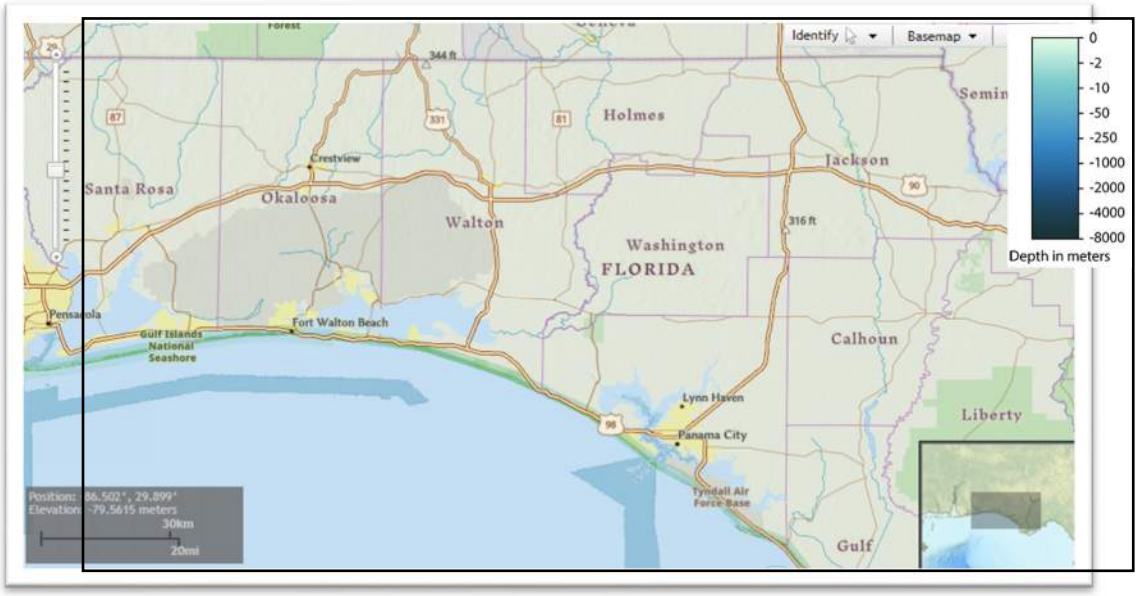

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle. Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

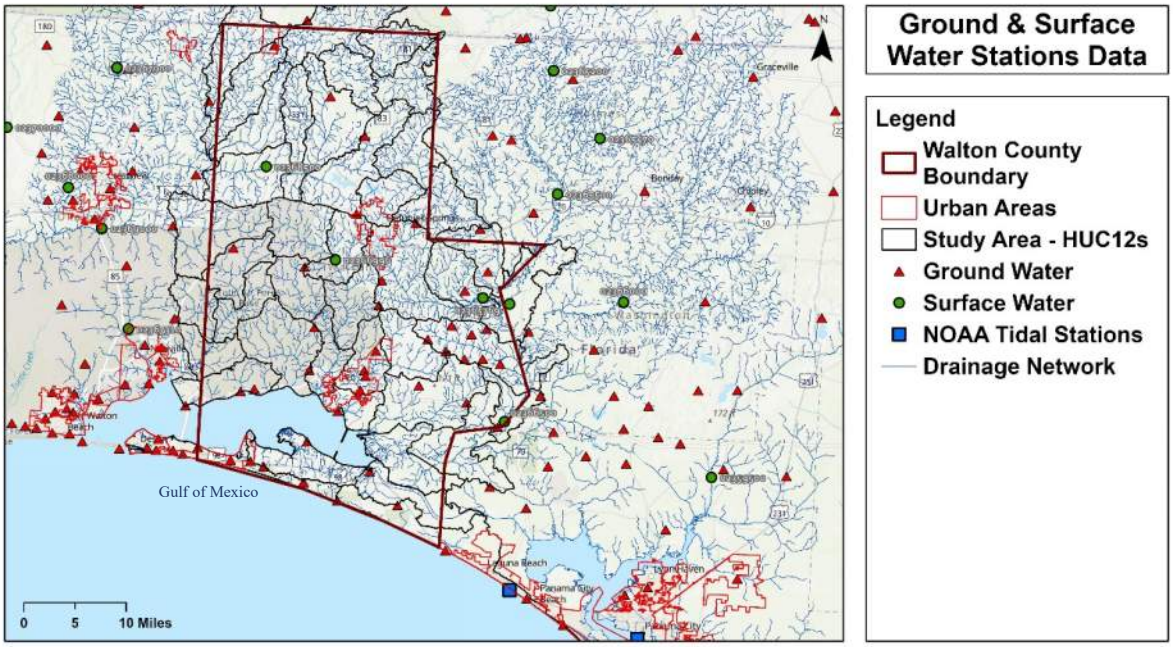

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031402020801 has no major rivers and canals, but well-branched creeks, which have no names.

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031402020801, which is USGS 02368500 Shoal River.

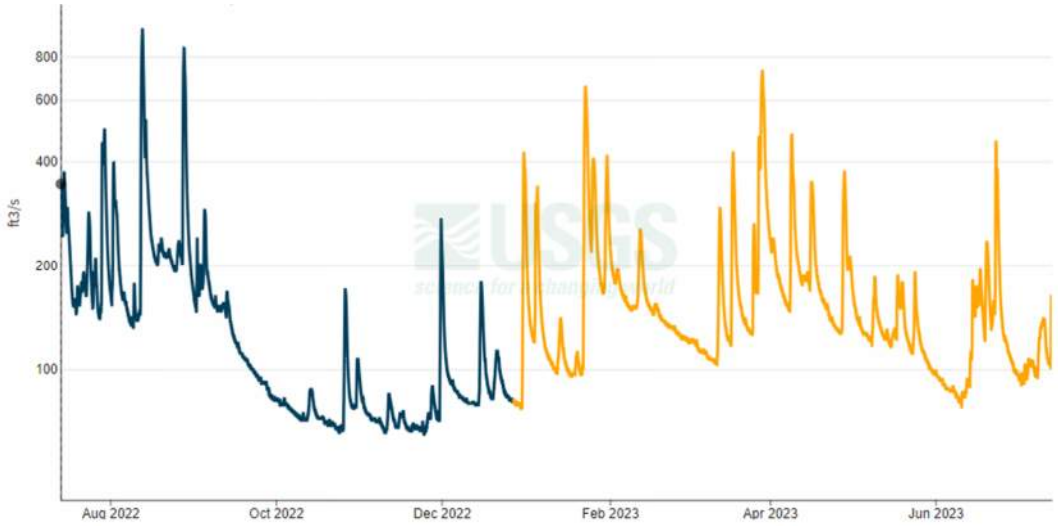

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031402020801 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031402020801 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

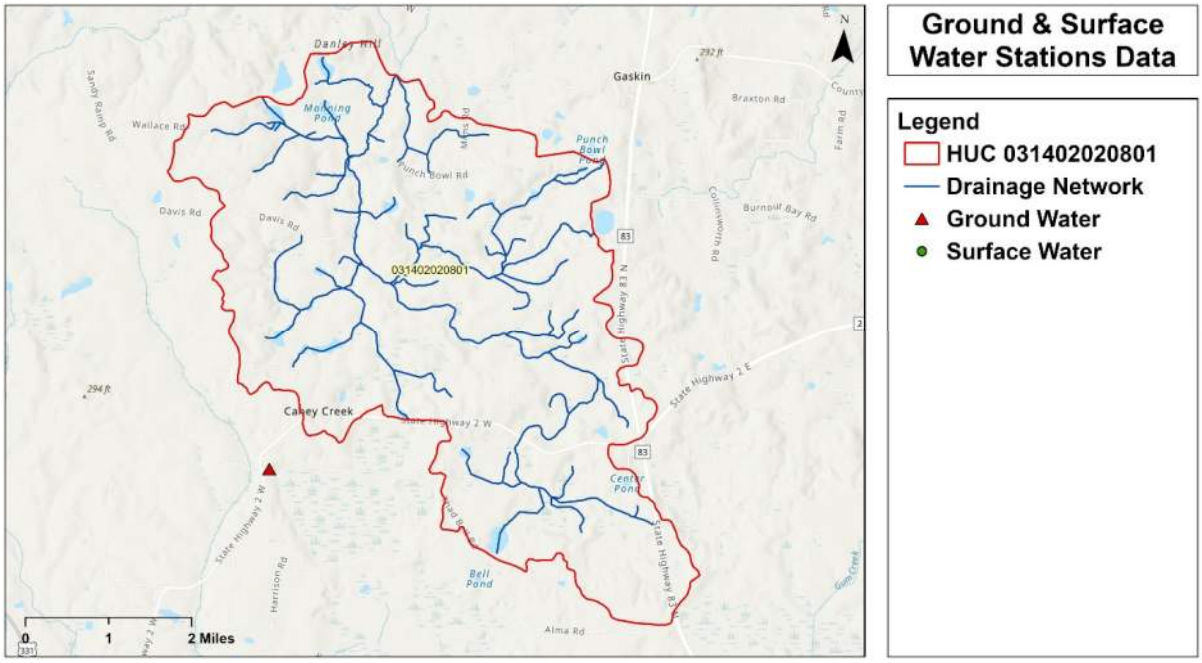

Figure 9. Ground and Surface Water Stations in the HUC 031402020801 sub-watershed, processed by FAU.

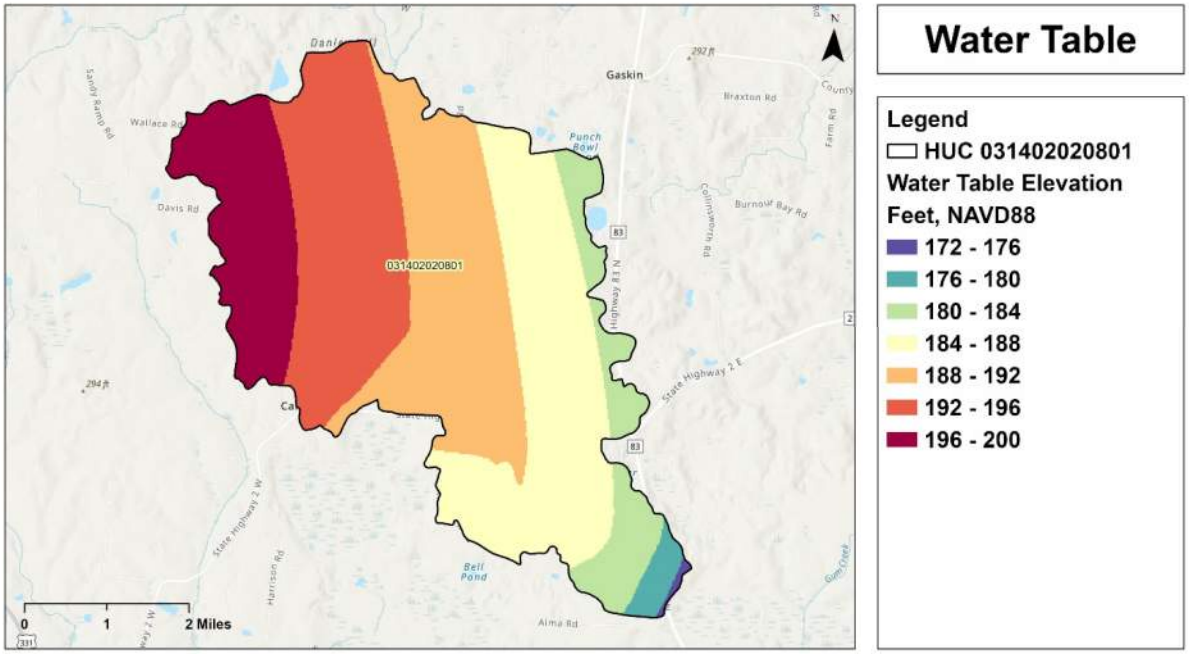

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031402020801 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the average precipitation over Walton County for every month of the year between 2011 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches for the entire county.

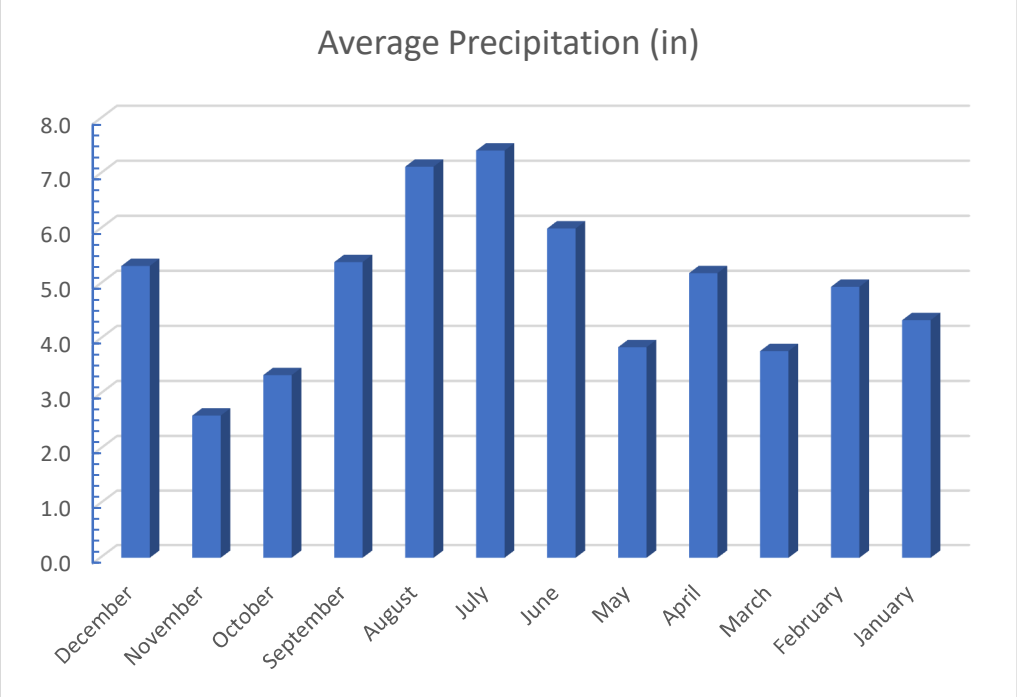

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as

opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. Figure 12 shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

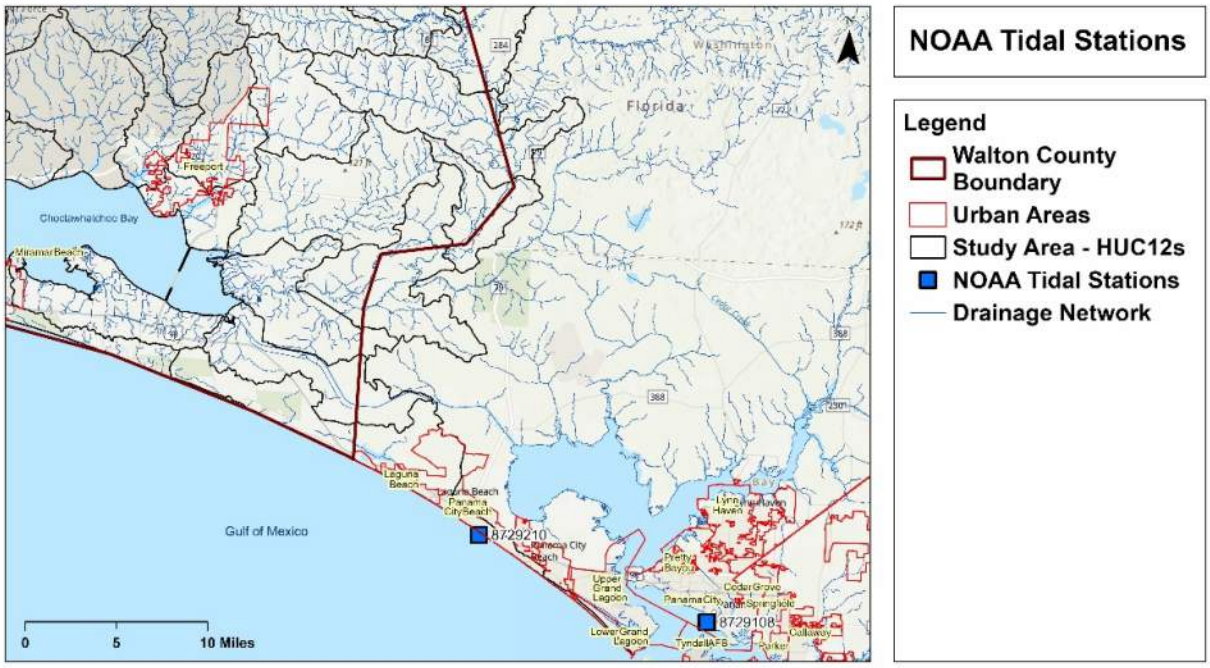

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

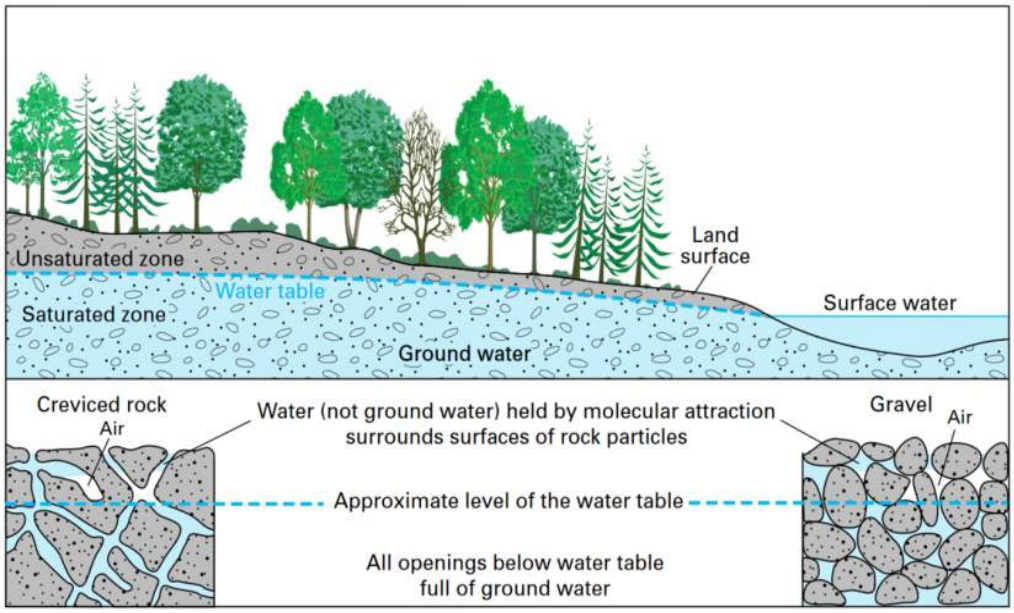

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

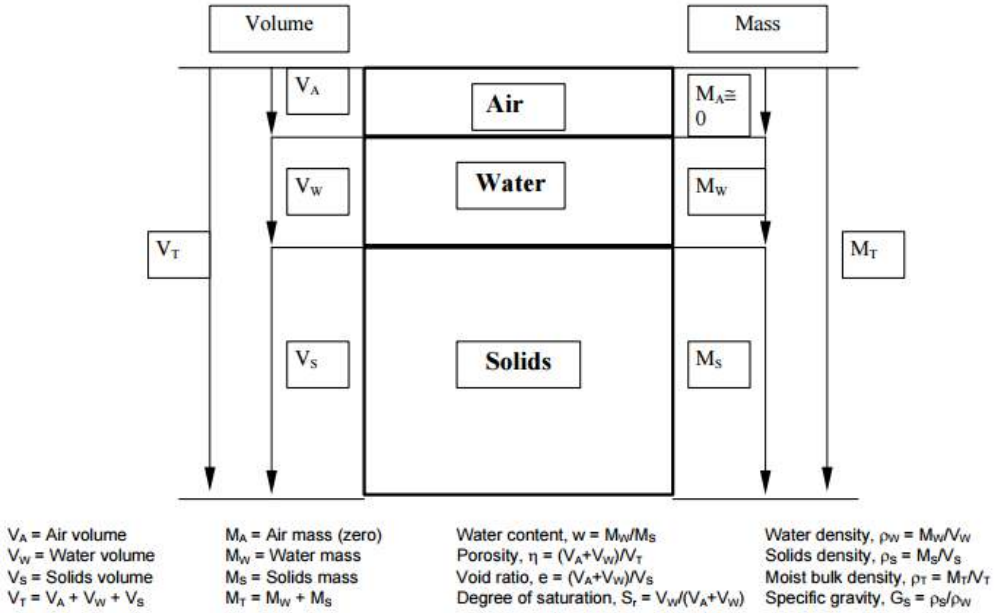

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

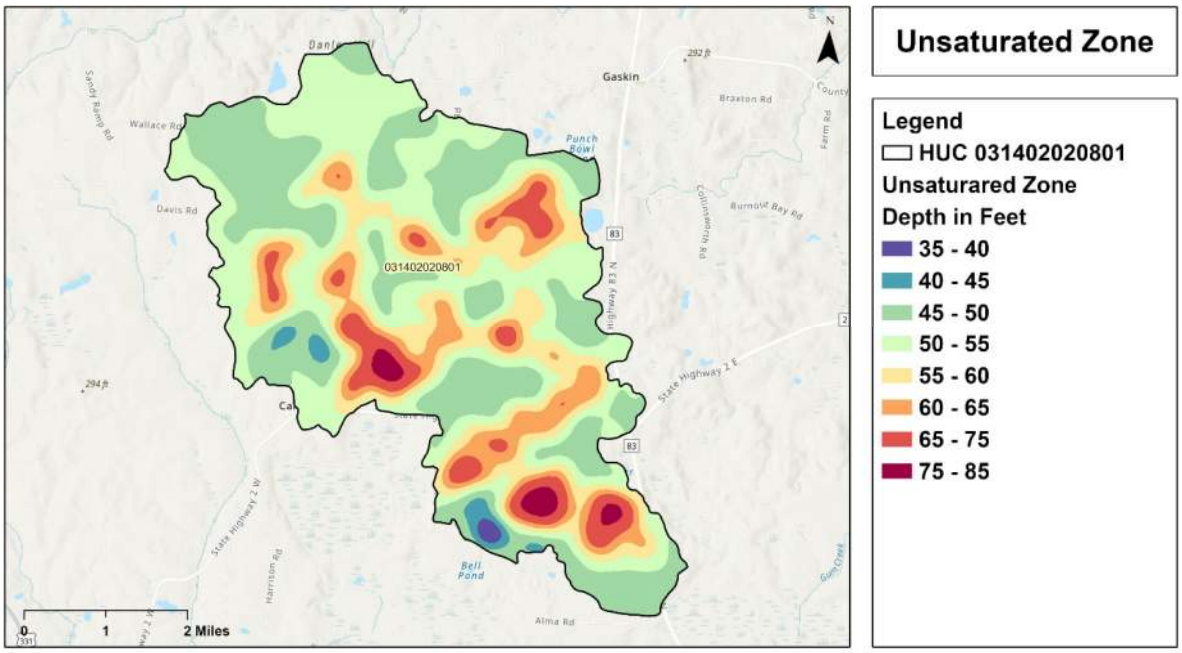

Figure 15. Unsaturated zone map for HUC 031402020801, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin exhibits a favorable soil storage capacity, ranging between 45 to 75 inches of remaining capacity.

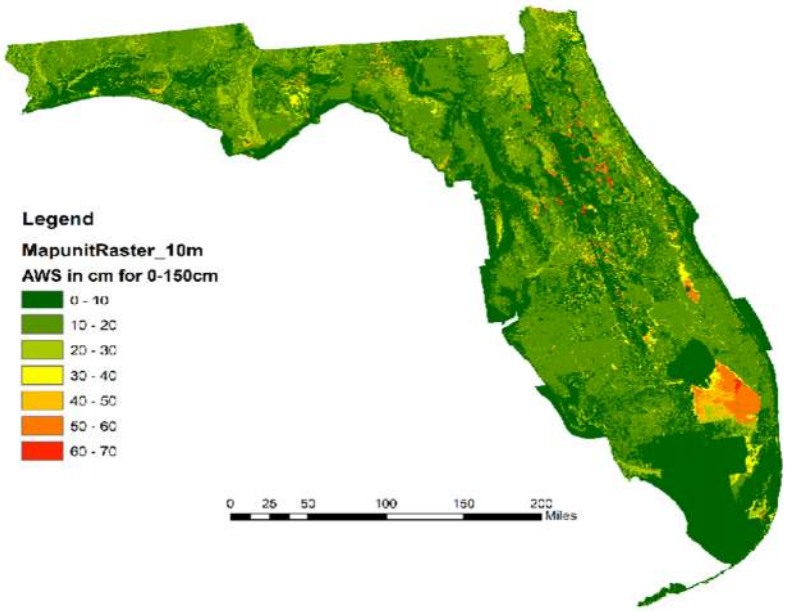

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

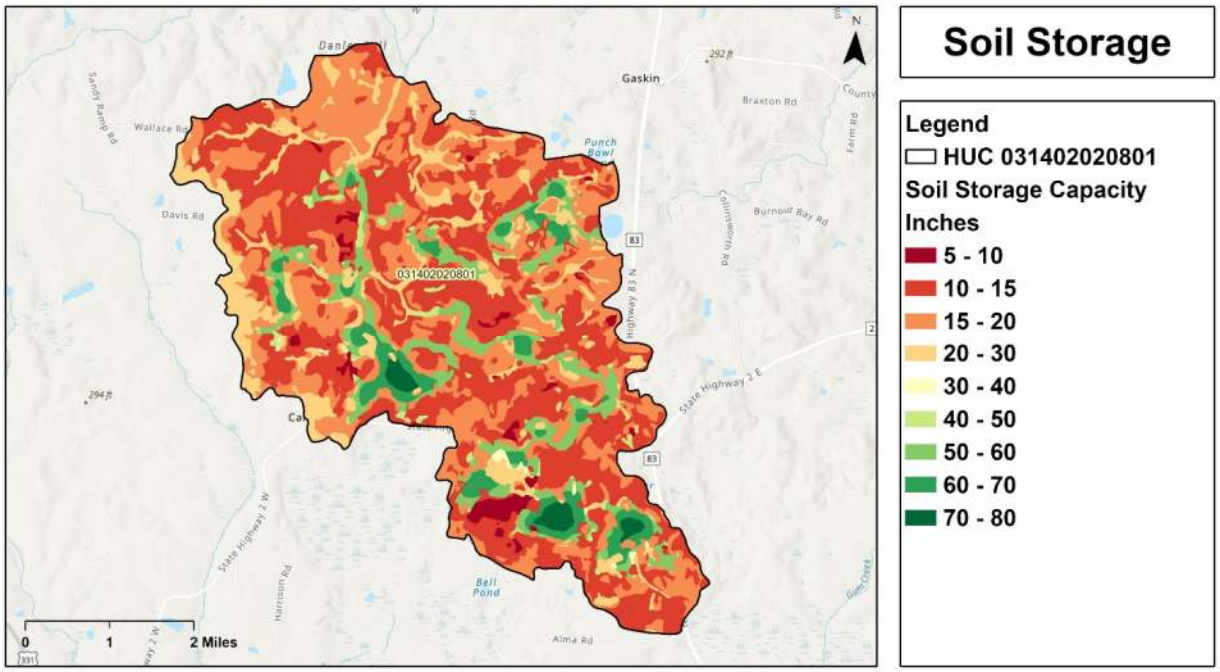

Figure 17. Water storage capacity of soil for the HUC 031402020801 (inches), processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

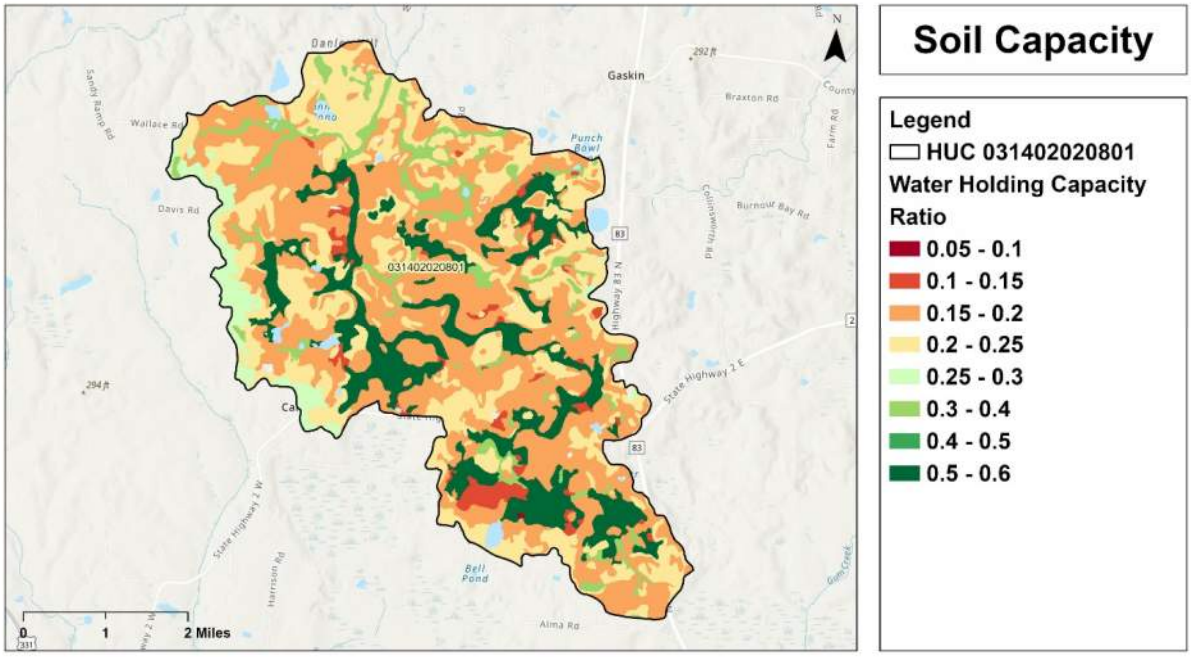

Figure 18. Water Holding Capacity (ratio) for the HUC 031402020801, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

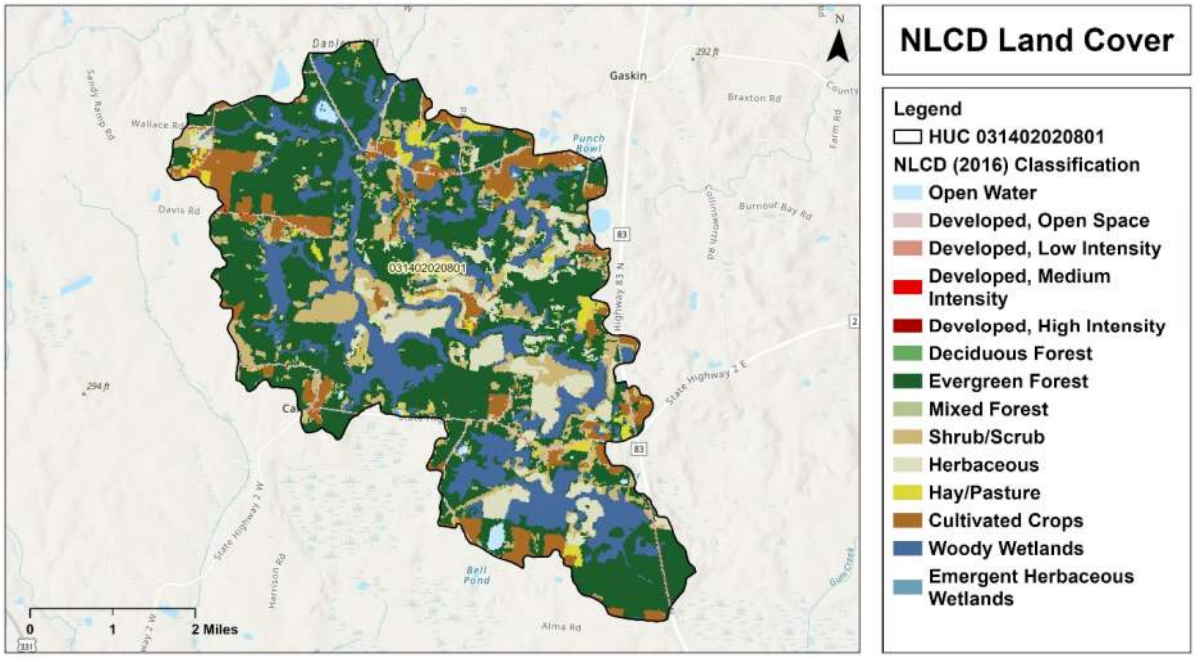

Figure 19. Land use in the HUC 031402020801 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD 2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

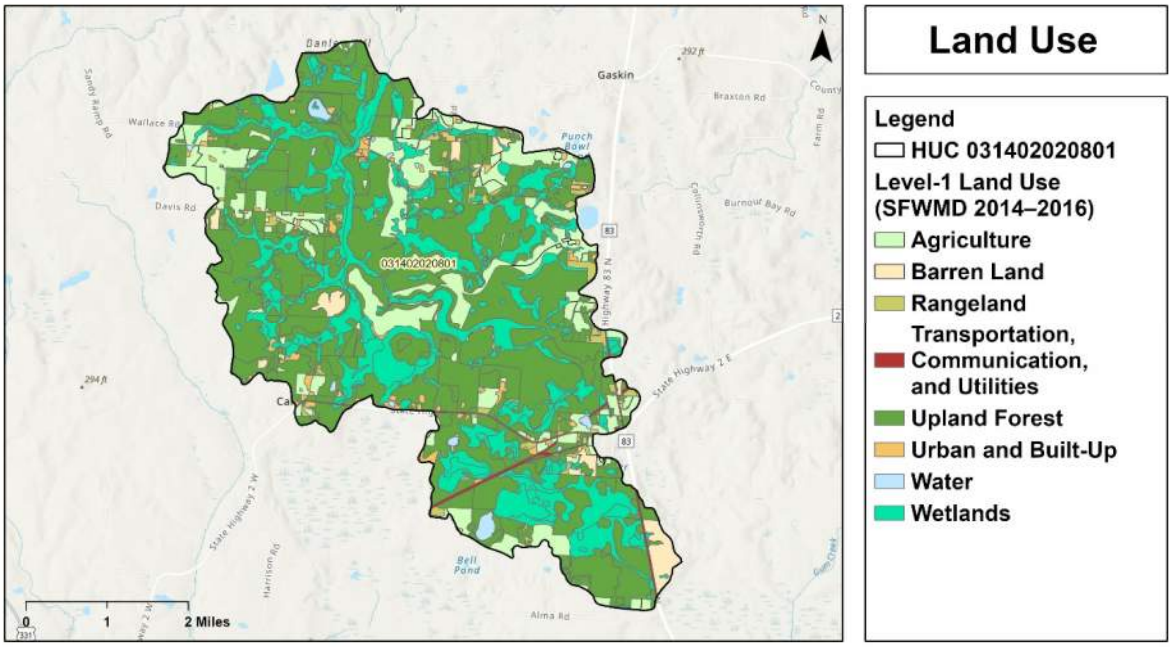

Figure 20. Land use in the HUC 031402020801 031401011001 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031402020801 sub-watershed, the predominant land cover is upland forest, accounting for 60.11% of the area. Transportation, Communication, and Utilities comes in second at 16.24%, followed by wetlands at 10.64%. Developed land constitutes a minor portion, with only 2.16% categorized as urban and built-up, as indicated in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031402020801 subwatershed

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	121.92	0.42%
Barren Land	75.01	0.26%
Rangeland	2849.14	9.93%
Transportation, Communication, and Utilities	4662.31	16.24%
Upland Forest	17254.18	60.11%
Urban and Built-Up	620.10	2.16%
Water	66.22	0.23%
Wetlands	3055.21	10.64%
Grand Total:	**28704.07**	**100.00%**

(Source Data: 2023 Florida Geographic Data Library (FGDL) database))

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

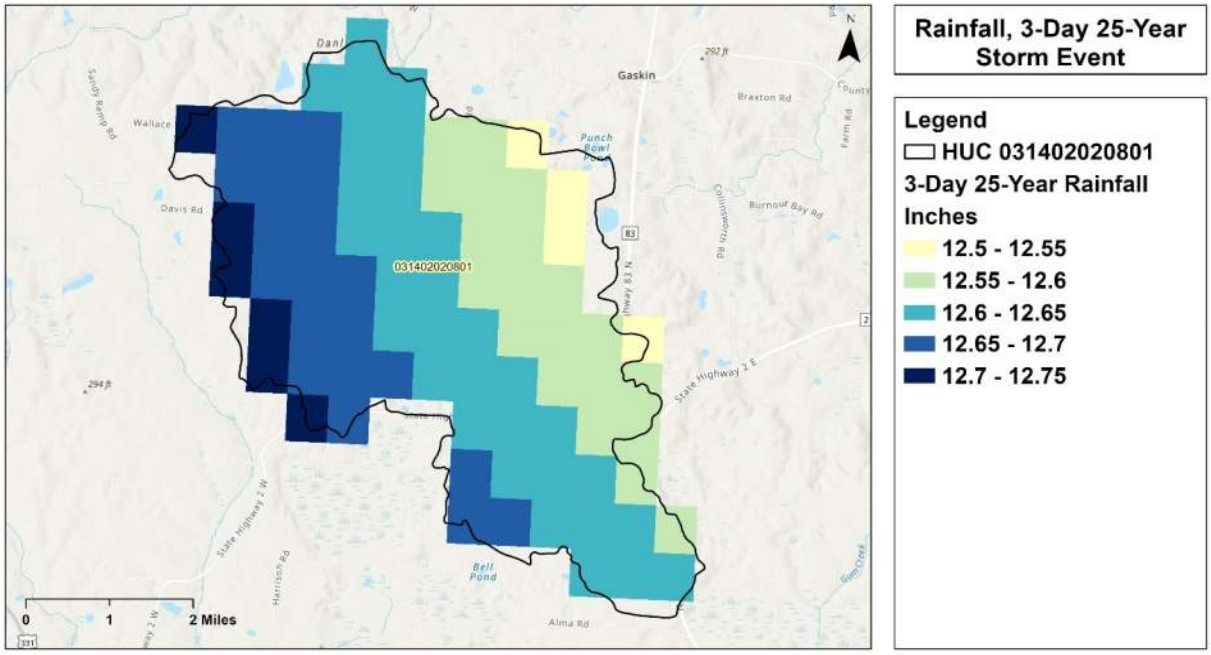

Figure 21. Rainfall distribution map across HUC 031402020801 sub-watershed, for 3-day 25-year storm event, processed by FAU.

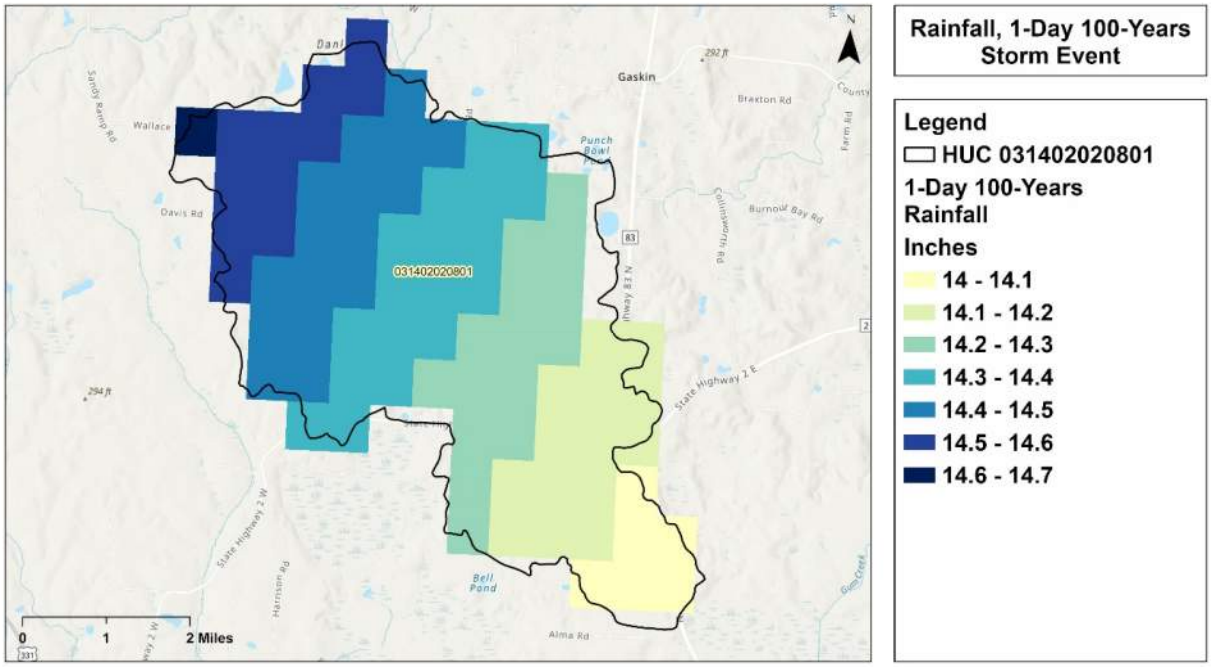

Figure 22. Rainfall distribution map across HUC 031402020801 sub-watershed, for 1-day 100-year storm event, processed by FAU.

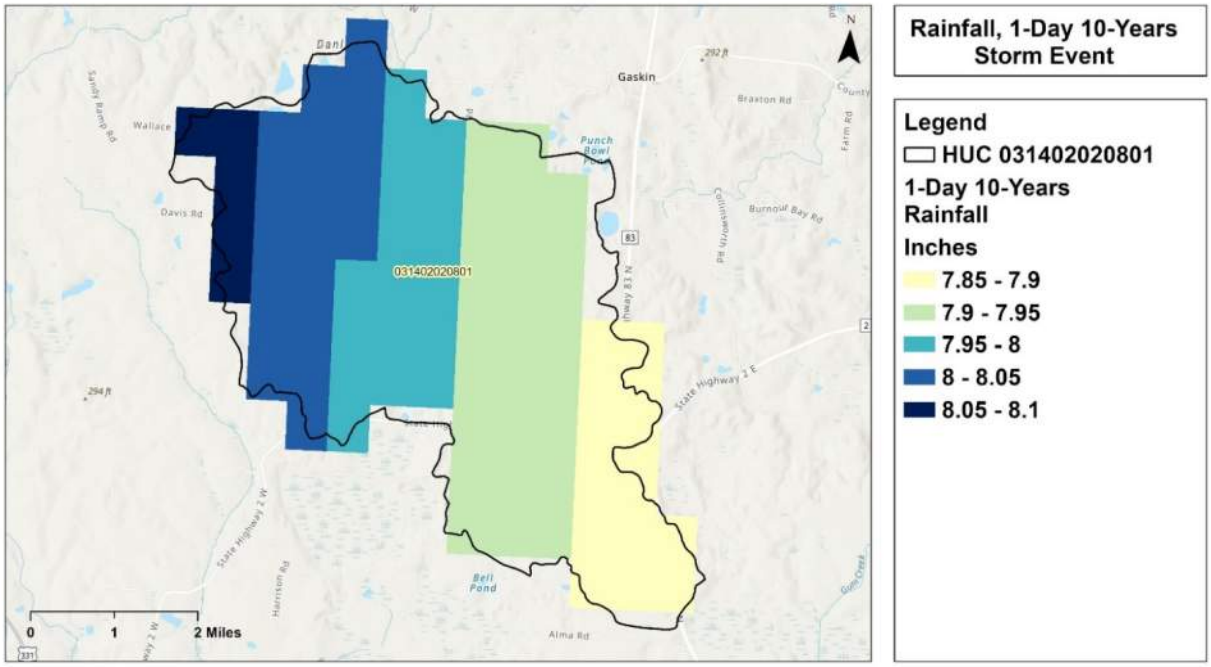

Figure 23. Rainfall distribution map across HUC 031402020801 sub-watershed, for 1-day 10-year storm event, processed by FAU.

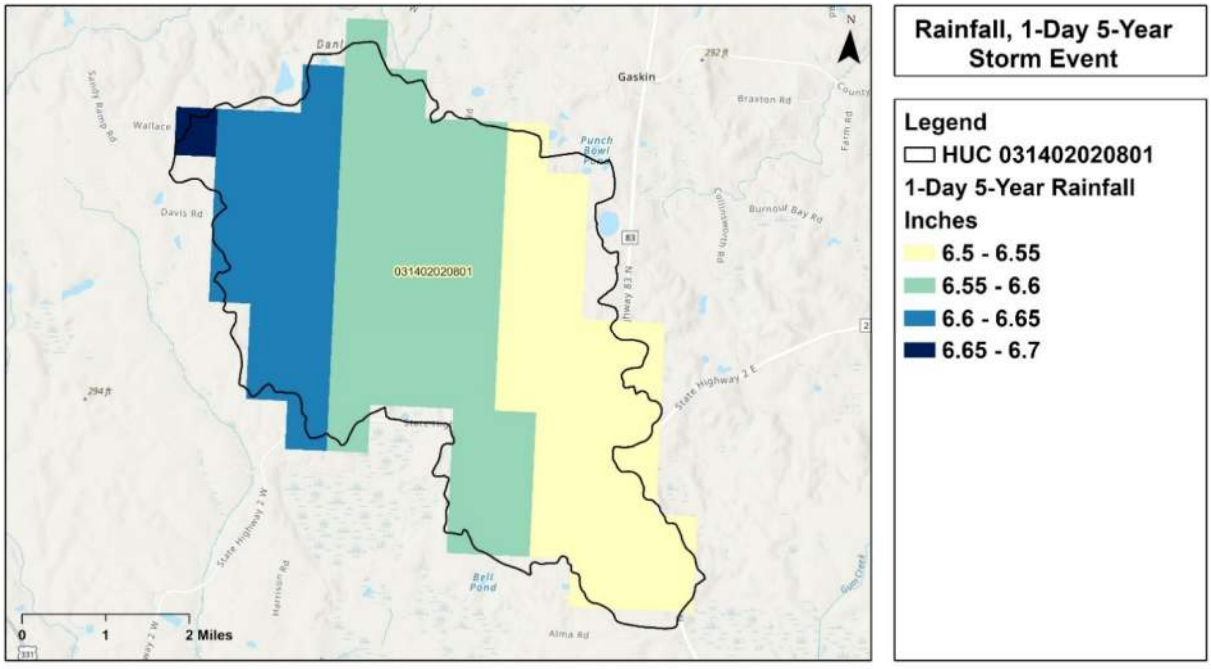

Figure 24. Rainfall distribution map across HUC 031402020801 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

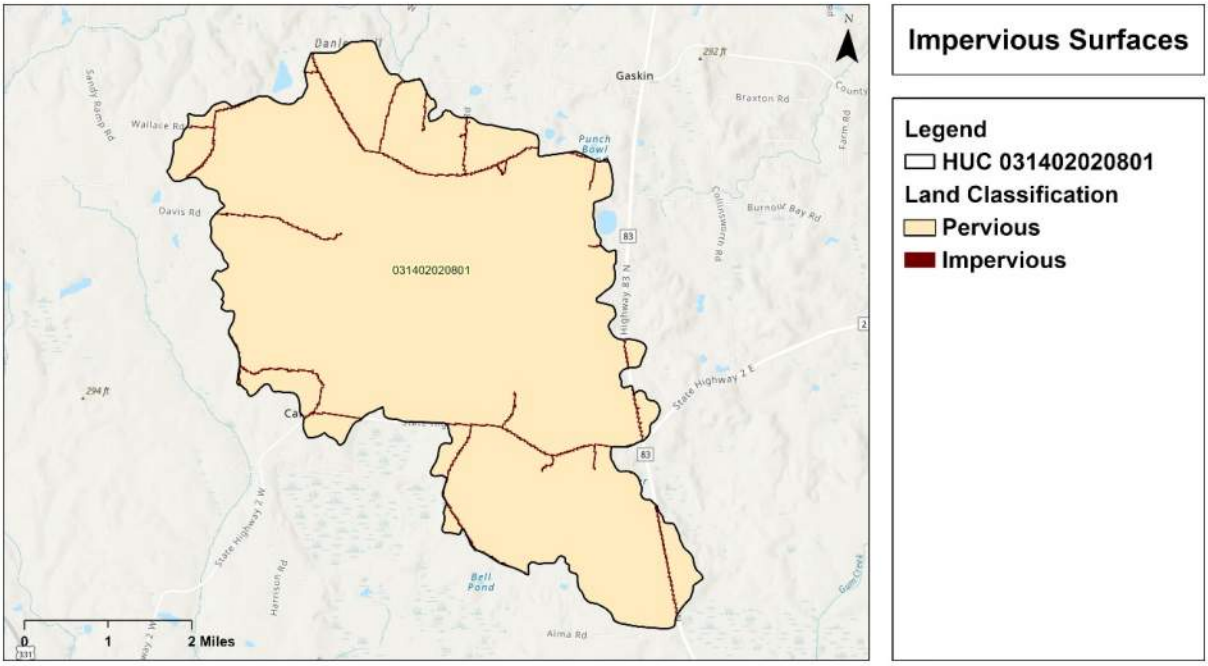

Figure 25. Impervious area map for the HUC 031402020801 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

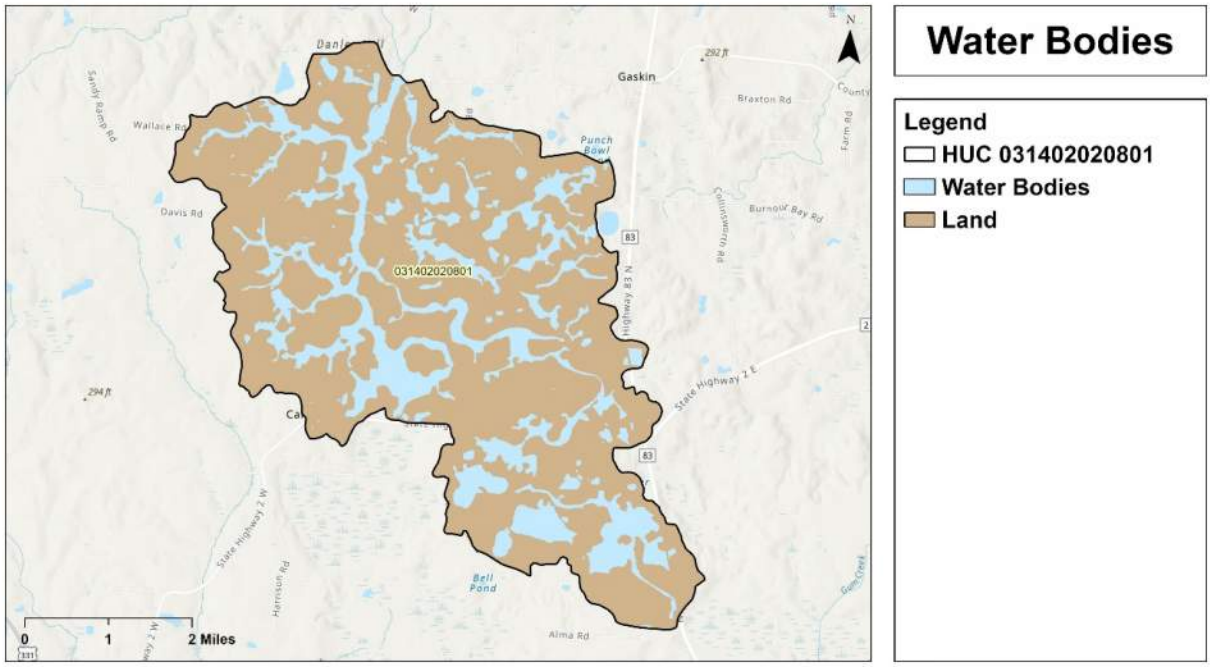

Figure 26. Water bodies map for the HUC 031402020801 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County
Area in square miles	7.02	18.94	13.95	4.01	17,021	68,722	1,038.29
Population (Census 2020)	8,002	5,861	5,919	556	2,878	20,567	75,305
Total Households	4,334	2,206	2,509	316	1,318	8,275	30,182
Median Household Income	$75,347	$75,637	$53,984	$41.750	$127,148	$94,648	$68,111
Median Age	56.3 years	41.4 years	37.1 years	50.6 years	52.4 years	43.20 years	45.0 years
White	7,688	2,086	4,021	482	2,638	17,268	89.8%

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.
- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

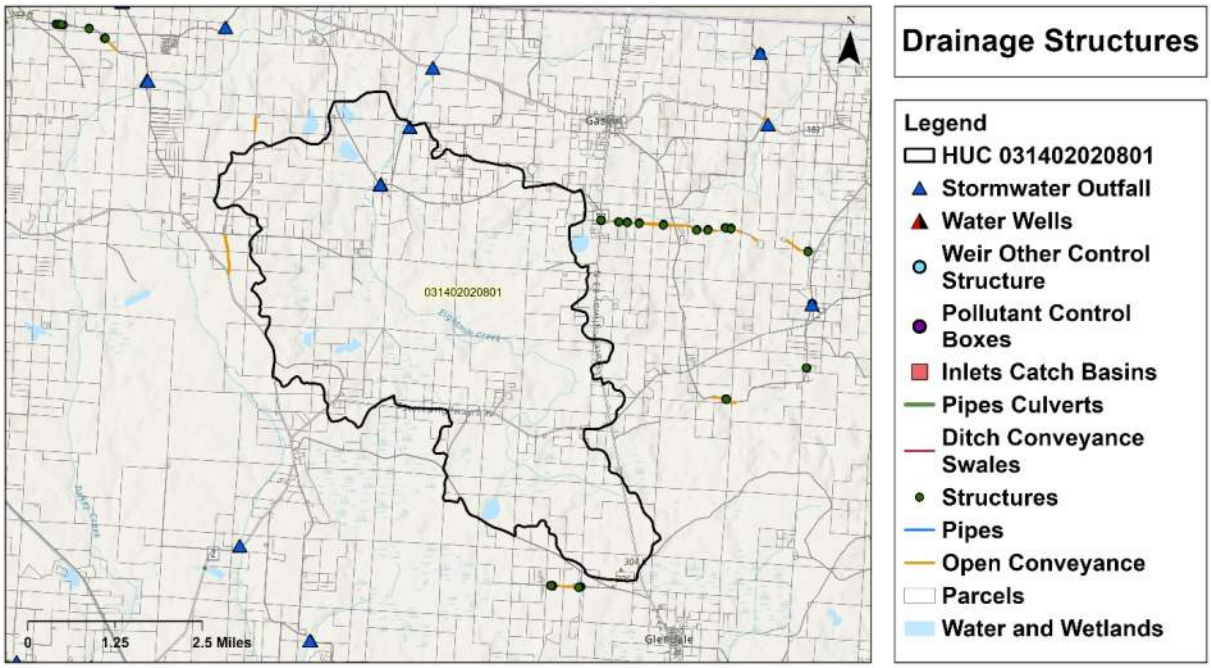

Figure 27. Stormwater Infrastructure for the HUC 031402020801. Processed by FAU.

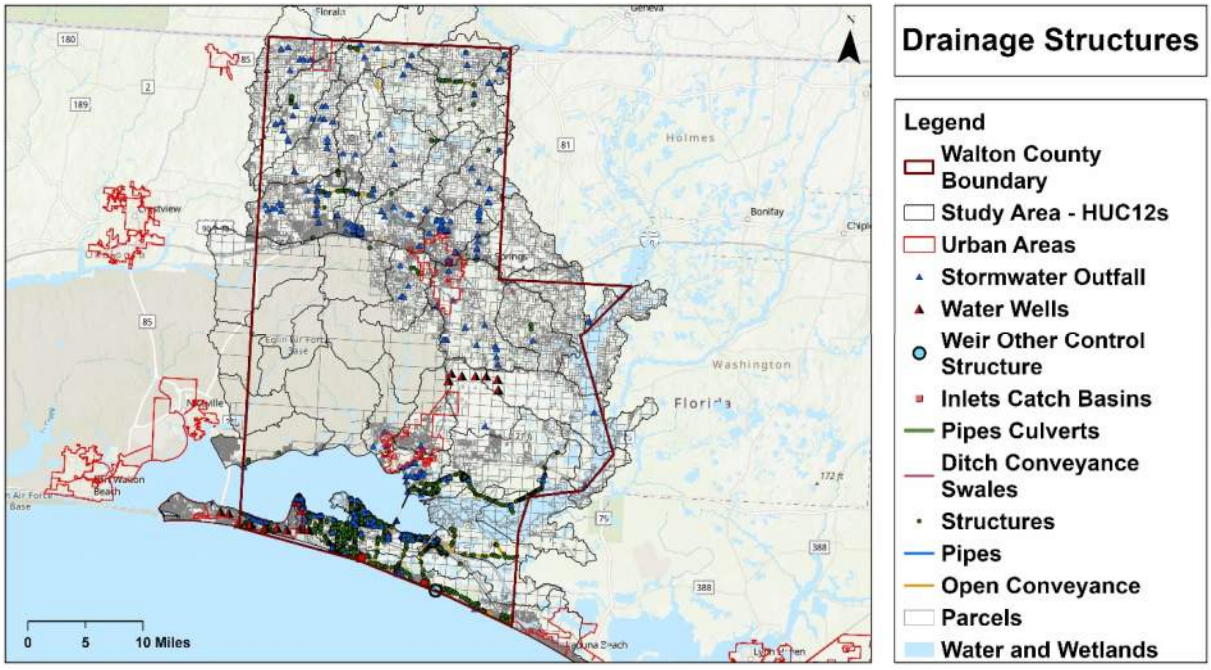

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapters 1, an analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned

urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031402020801 sub-watershed flood response to a series of rainfall events and sea levels (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.3.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

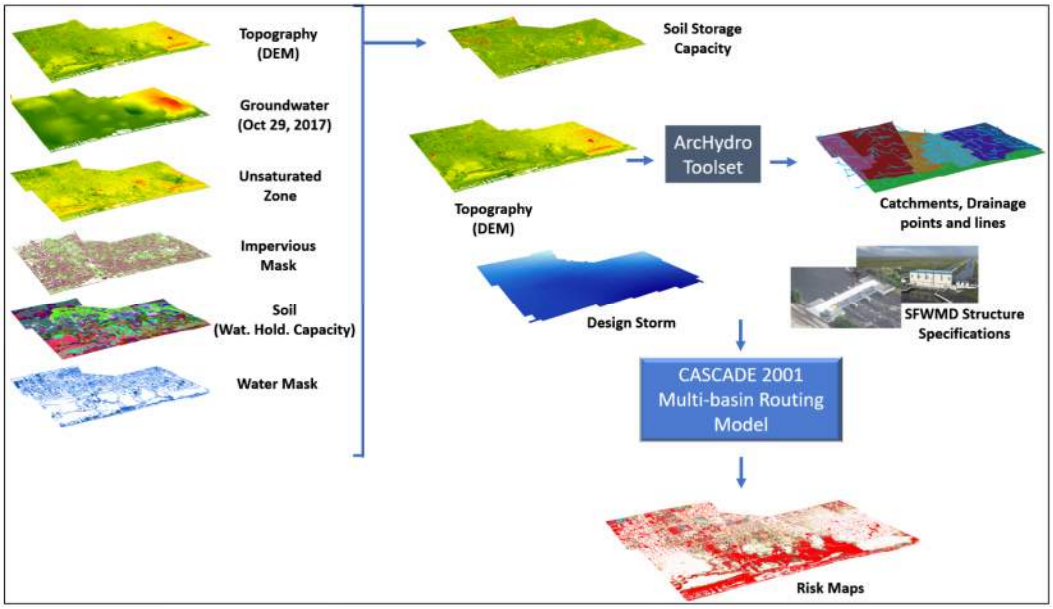

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (Figure 30), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

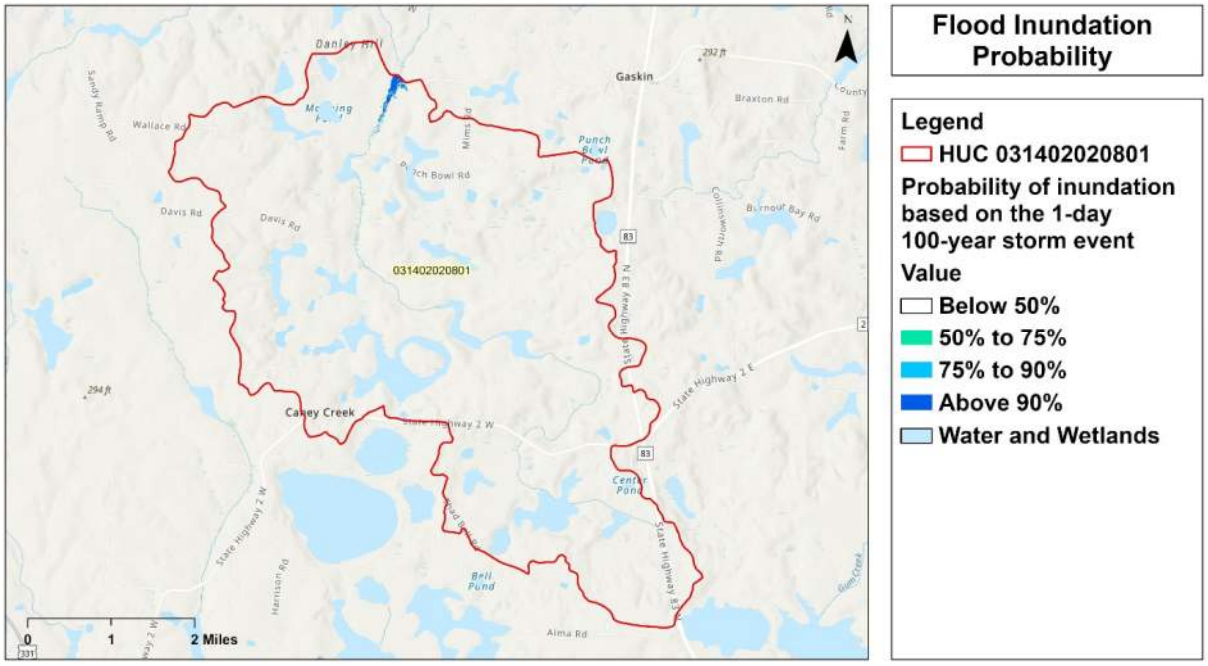

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031402020801, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation

and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 2.4 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations,

Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the creek entrance to the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 0.34% of the HUC total area or 0.078 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.18% of the HUC's total area, or 0.041 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.05% of the HUC's total area, or 0.013 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.04% of the HUC's total area, or 0.01 mi^2, would be expected to be inundated

during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 03140102020801 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	22.737	0.078	99.66%	0.34%
1-day 100-year	22.774	0.041	99.82%	0.18%
1-day 10-year	22.802	0.013	99.95%	0.05%
1-day 5-year	22.805	0.010	99.96%	0.04%

Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031402020801 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (Figure 35) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 36) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

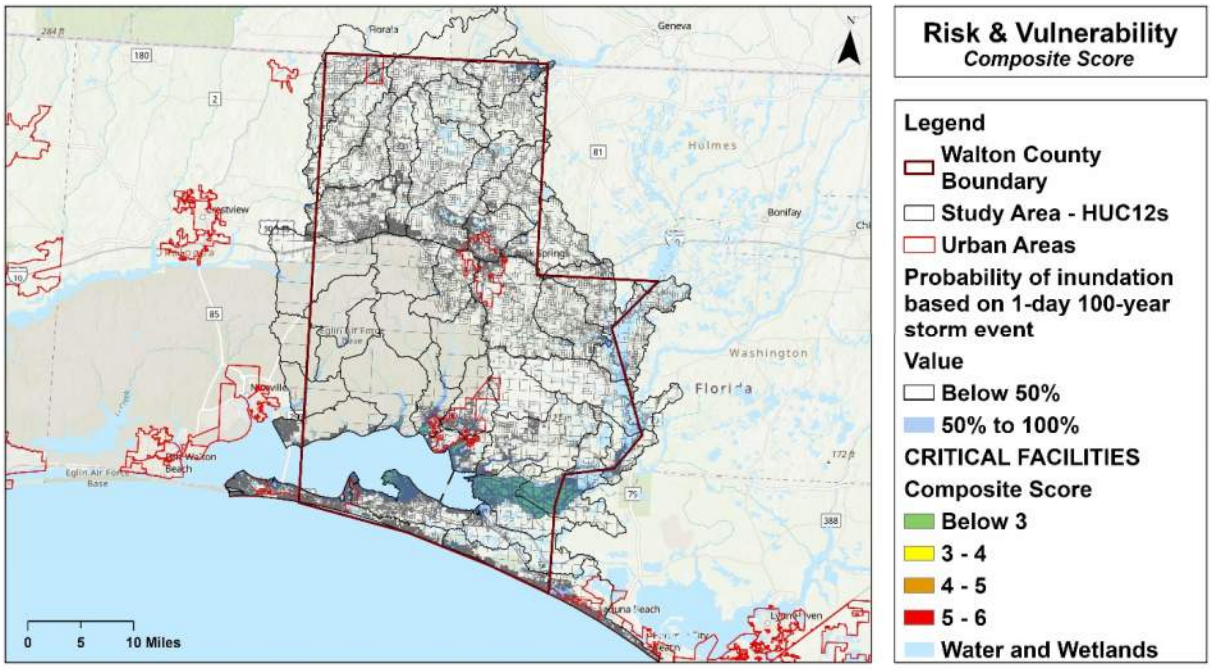

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031402020801. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031402020801. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031402020801	14601.58
All of the 1-day 100-year storm event inundation	**26.34**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	26.34
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	26.34

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

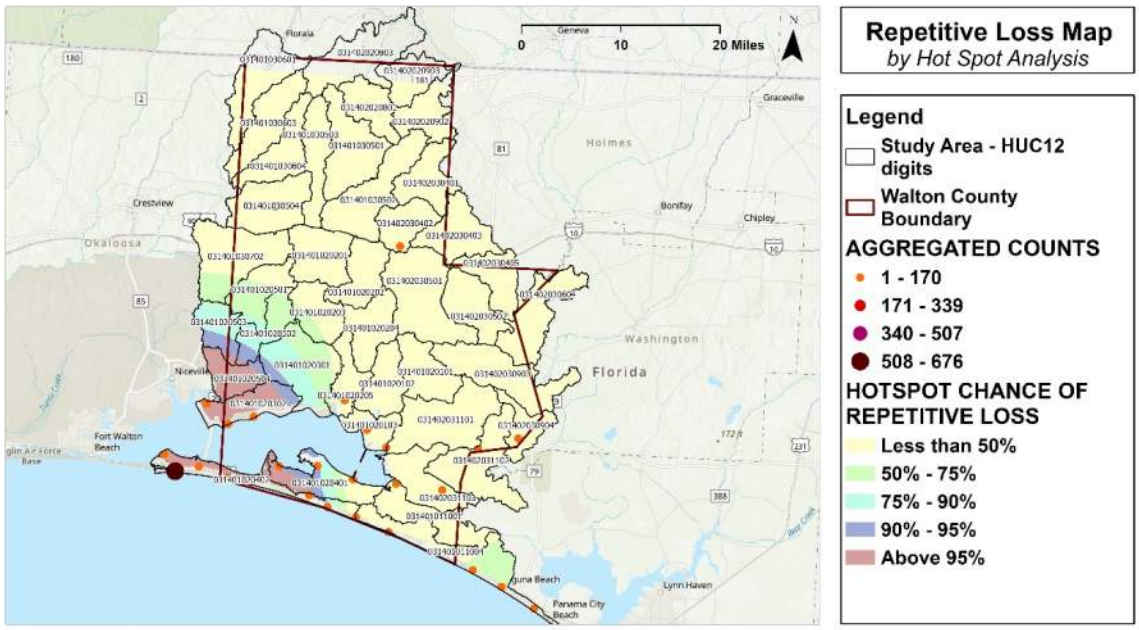

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are some parcels falling within tiers 2 (roads), 3, 4, and 5 of priority land uses, none of them are within the flooding zone, as the flooding in the area is minor and not alarming. Consequently, when considering the composite score, it is notable that most of the results are null, indicating no priority for intervention within the basin. There is only one exception within the basin, which is a mobile home parcel with a score below 3.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**,, the HUC-12 (031402020803) is highlighted among all the HUCs to help identifying its location (Figure 3). While a significant portion of this HUC's area lies within Walton County, Florida, the remaining portion, comprising slightly more than half, extends into the state of Alabama.

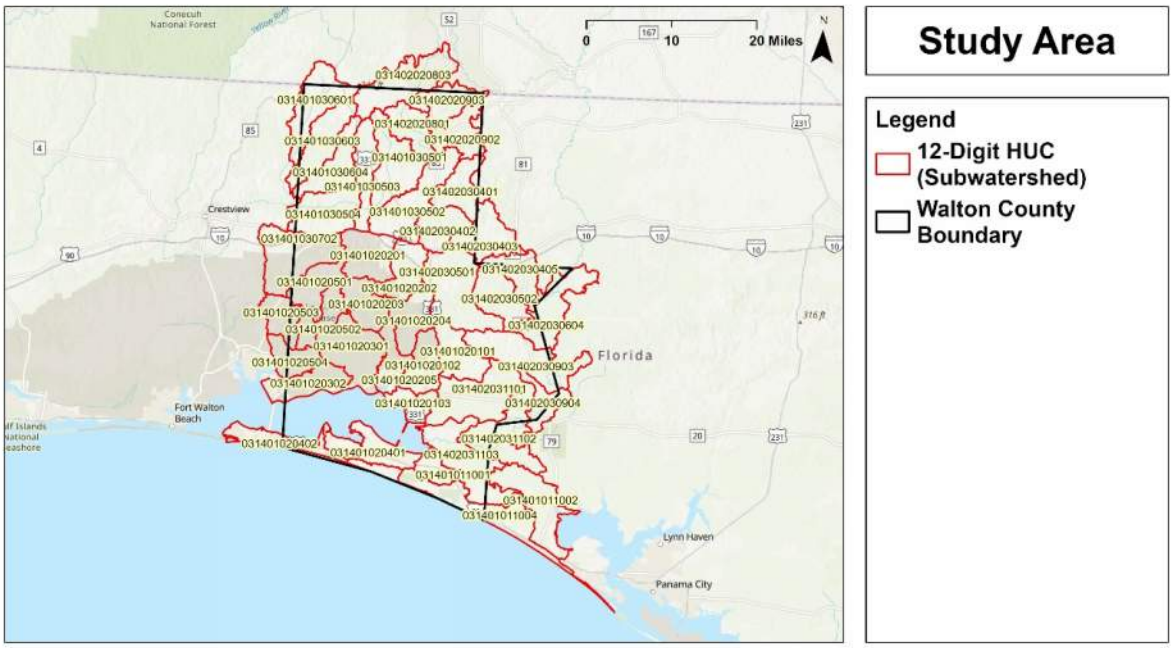

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

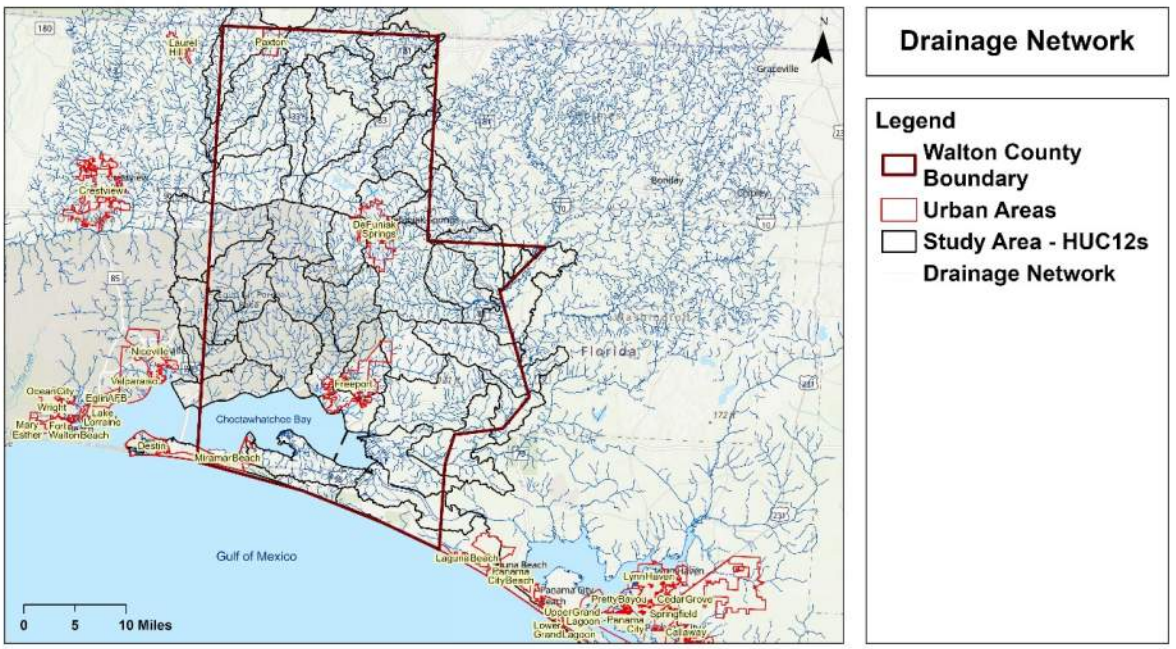

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

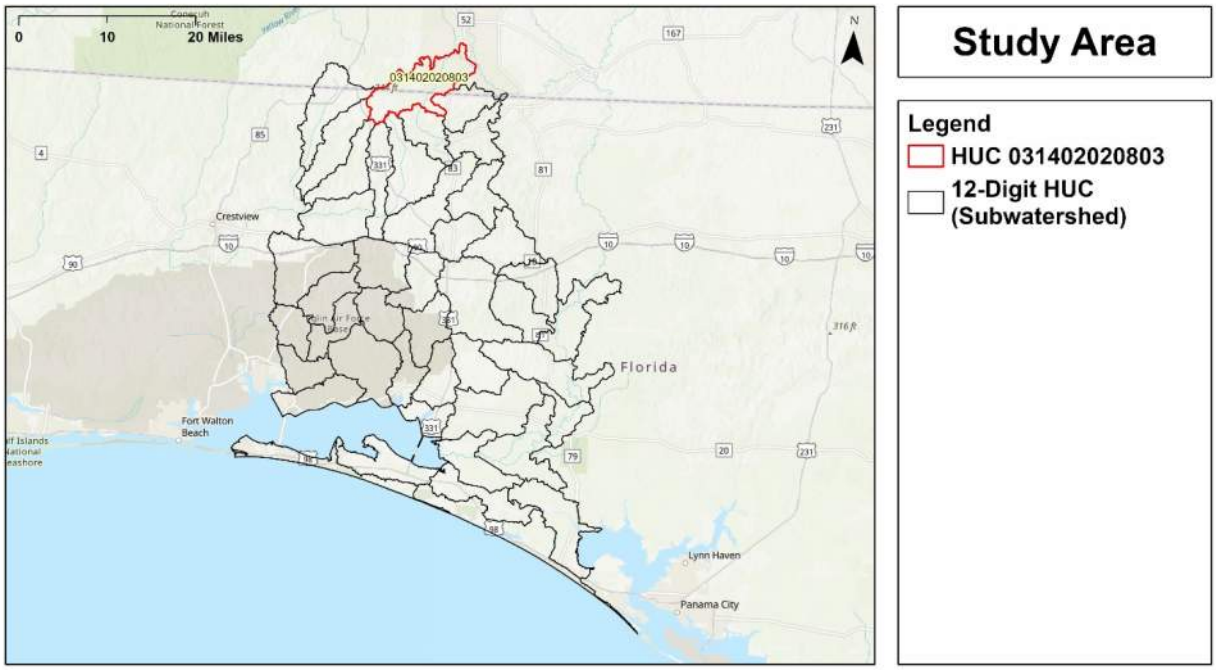

Figure 3. HUC 031402020803 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

(Source Data: FEMA)

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

(Source Data: NWFWMD, 2017)

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.

- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

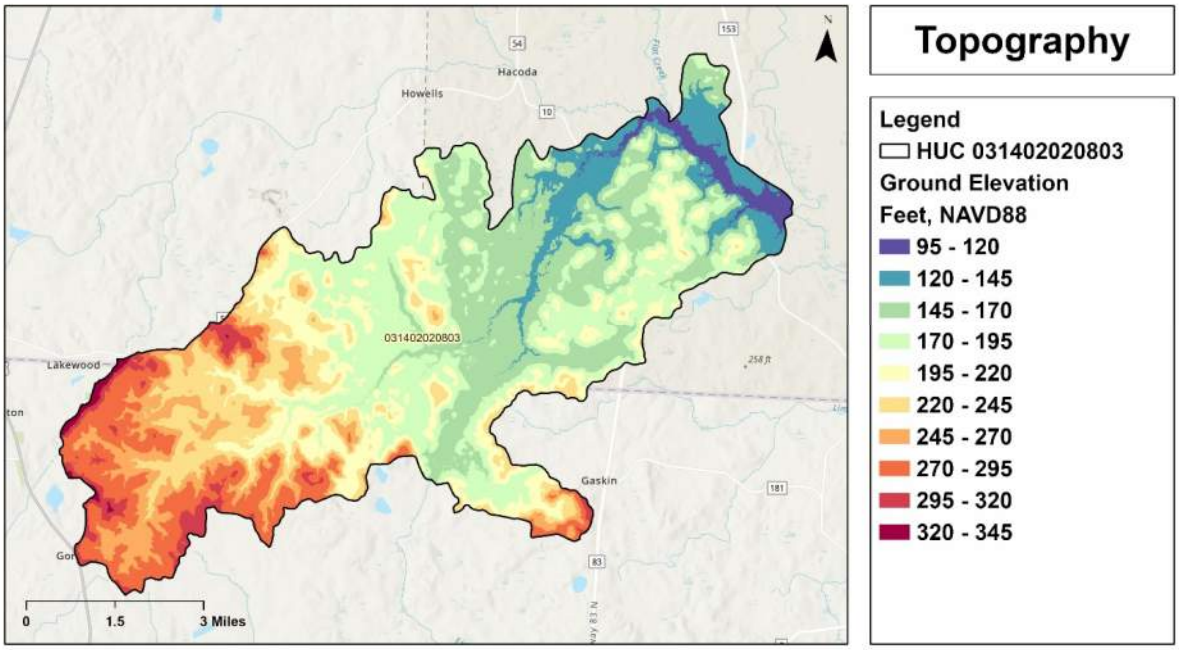

Figure 4. Topographic map of the HUC 031402020803 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031402020803 sub-watershed is shown in **Error! Reference source not found.**.

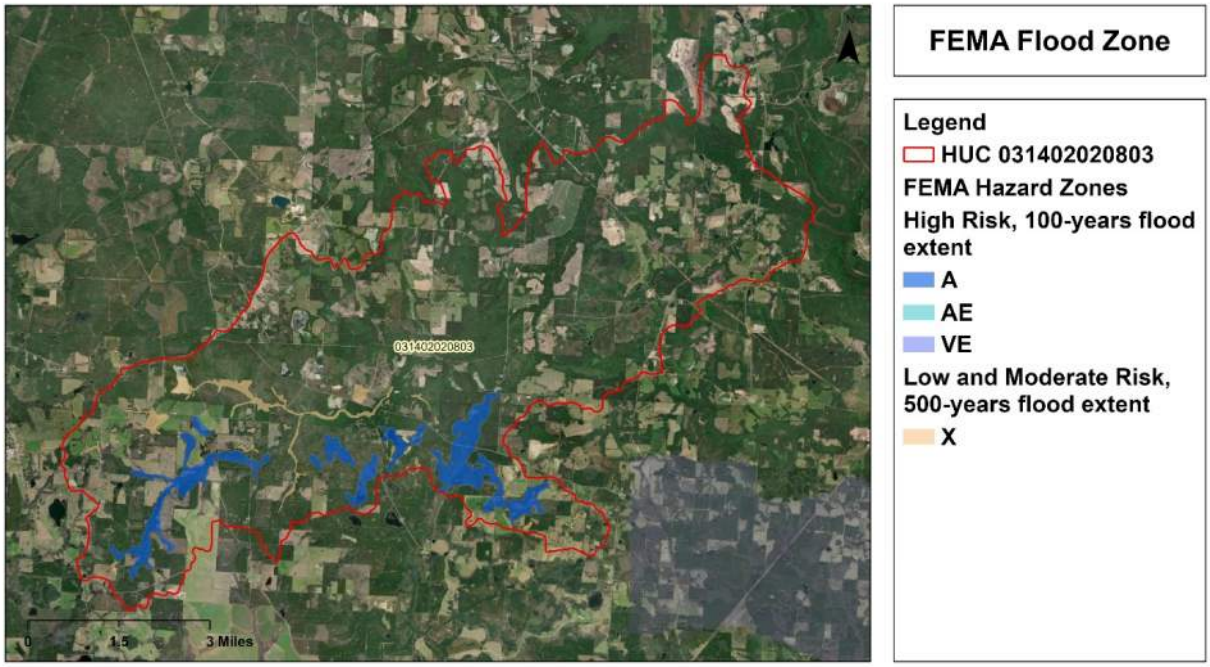

Figure 5. FEMA Flood Zone map (2020) for HUC 031402020803 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031402020803 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including

various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

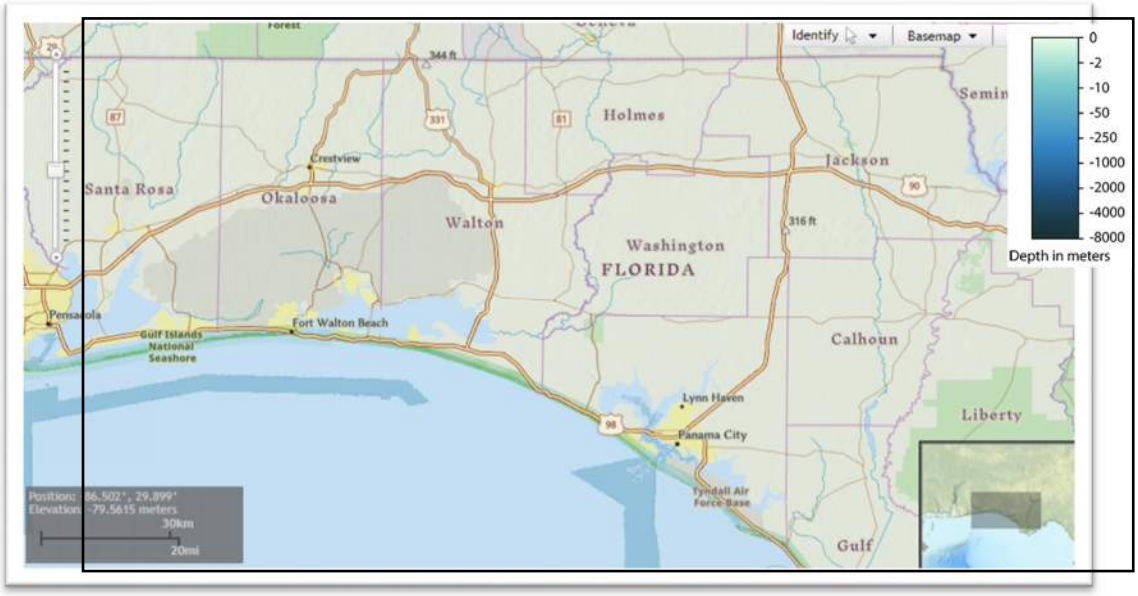

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle. Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

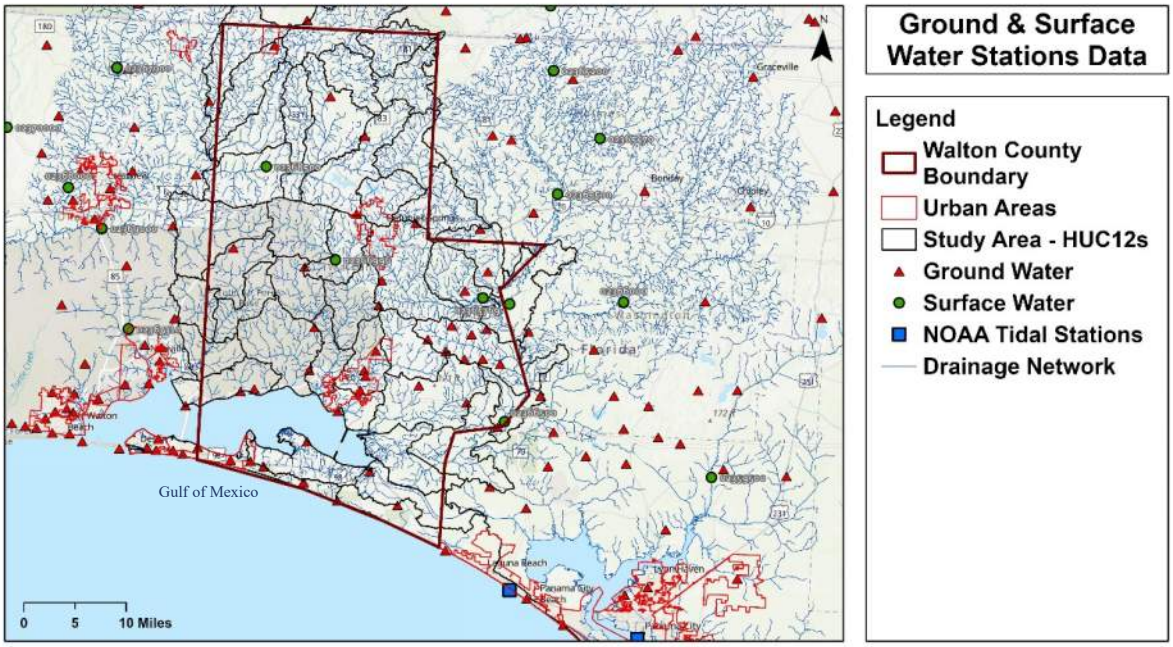

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031402020803 lacks major rivers and canals, instead featuring a network of well-branched creeks without specific names. These creeks originate from various directions and flow in different directions as well.

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031402020803, which is USGS 02368500 Shoal River.

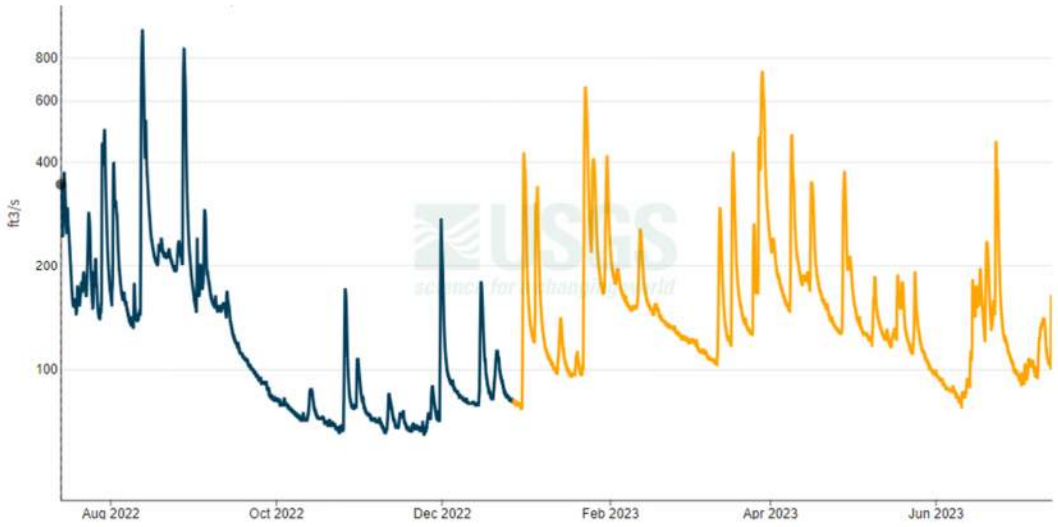

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu.. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031402020803 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031402020803 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

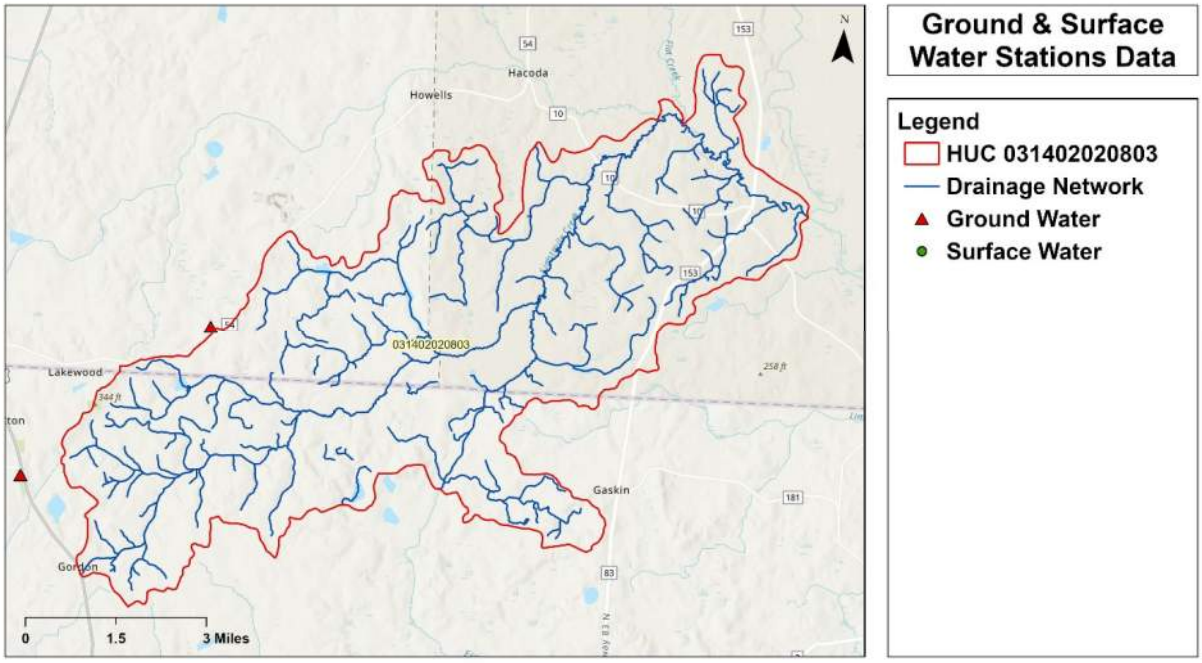

Figure 9. Ground and Surface Water Stations in the HUC 031402020803 sub-watershed, processed by FAU.

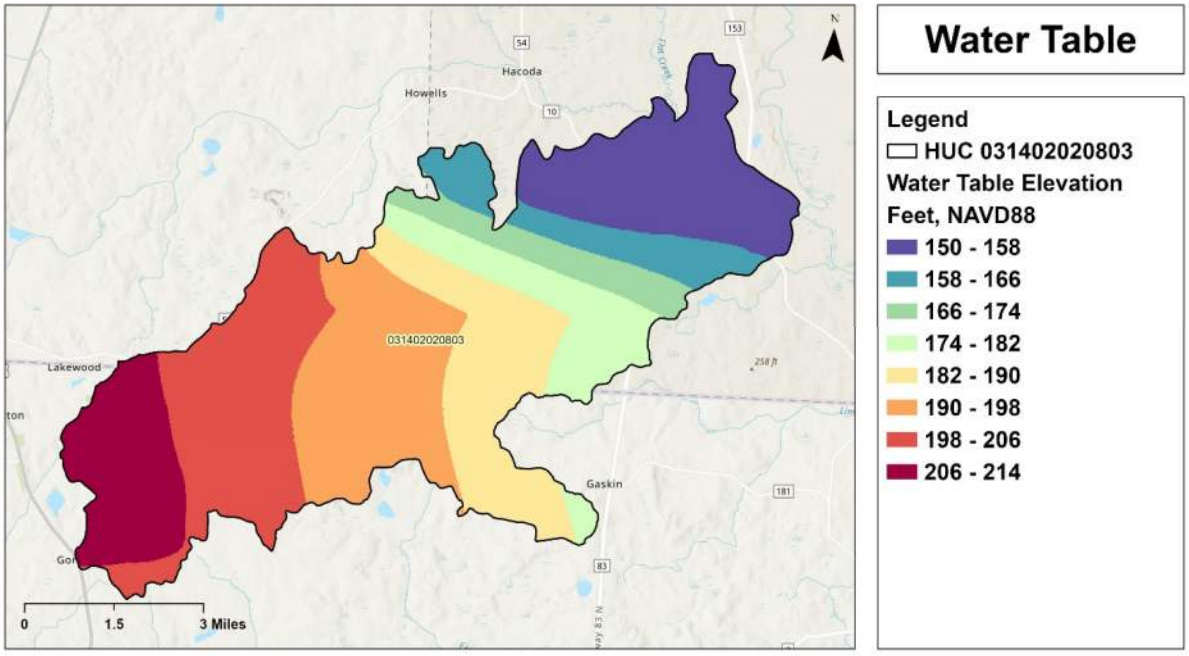

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031402020803 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows average precipitation over Walton County for every month of the year between 2011 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches for the entire county.

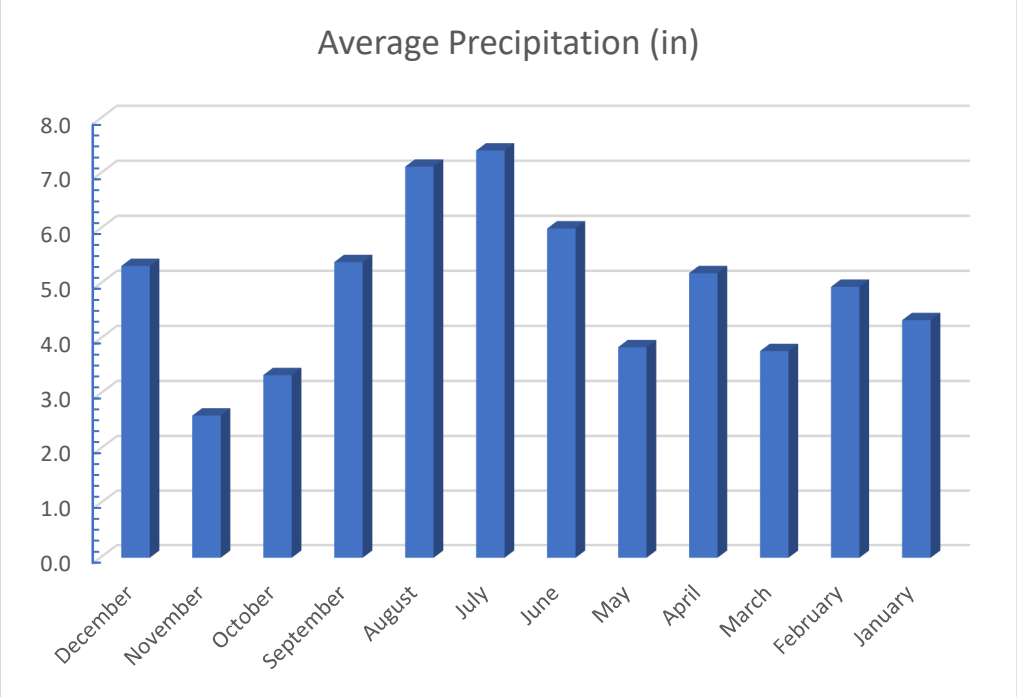

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4)create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as

opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. Figure 12 shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

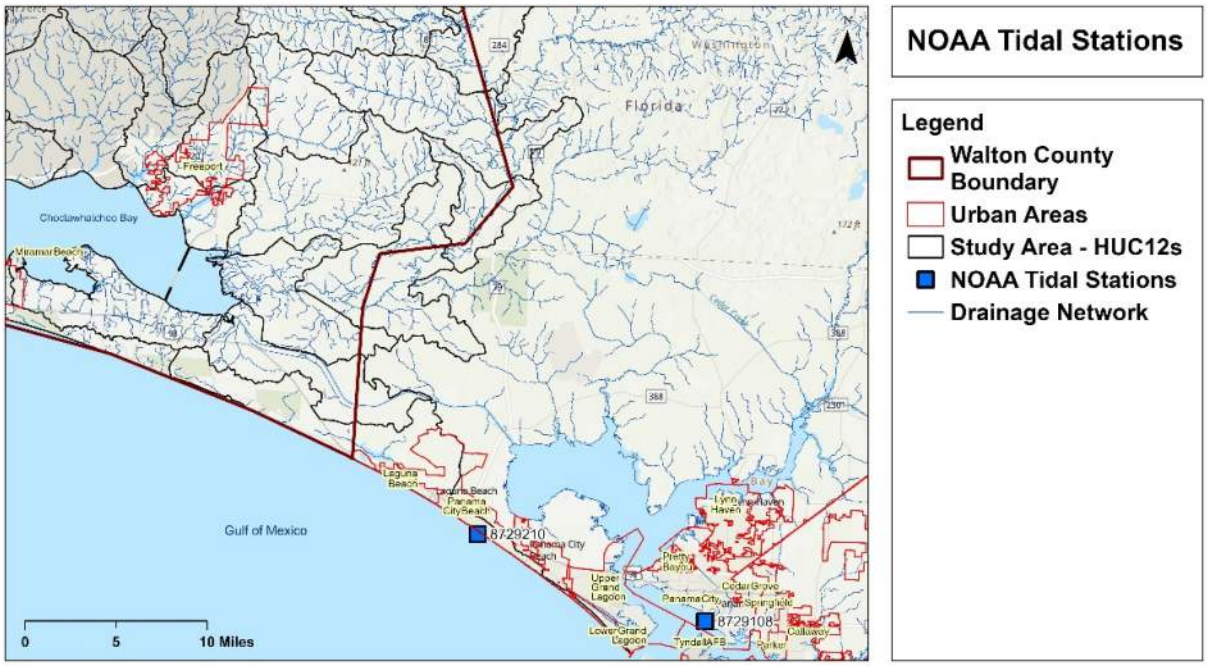

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

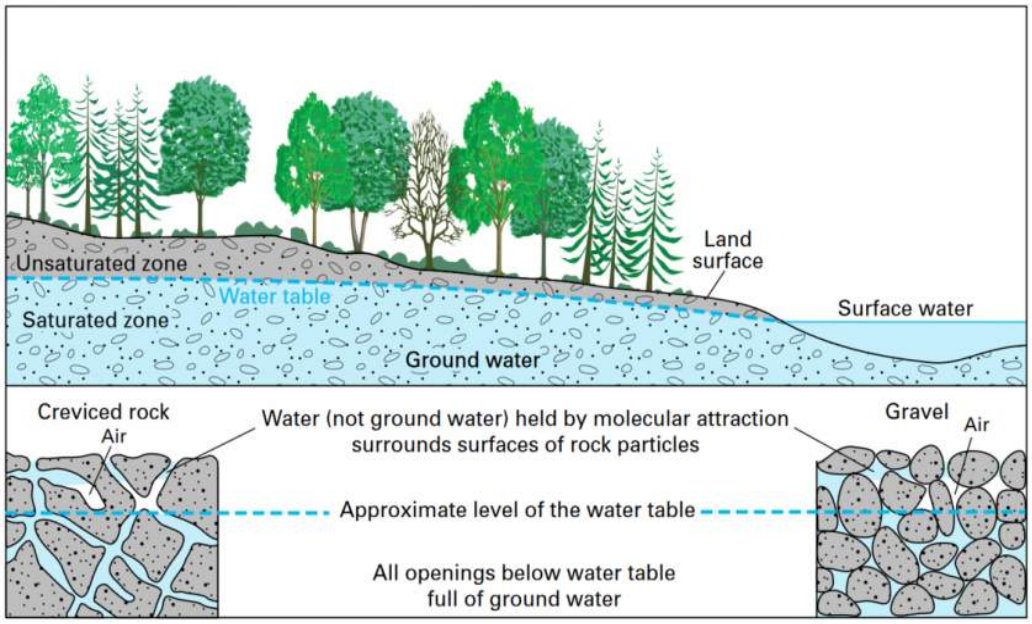

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

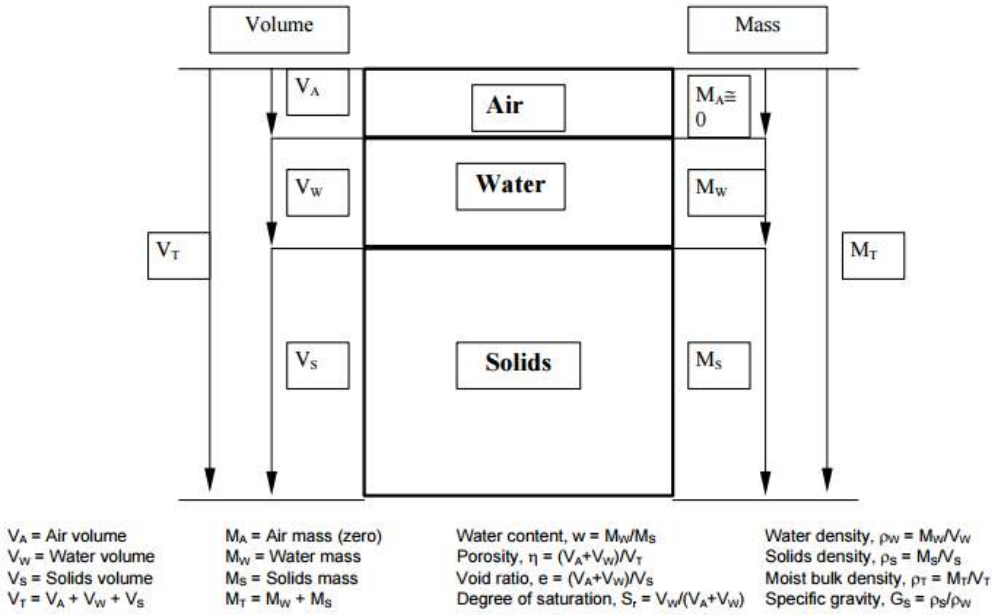

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

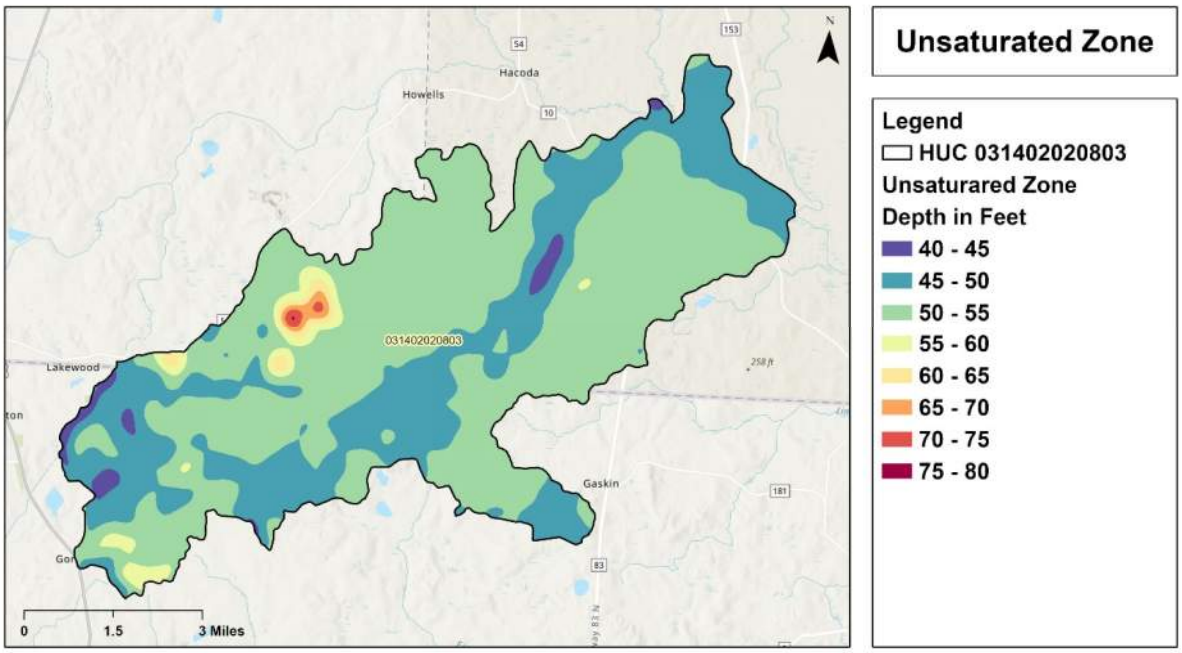

Figure 15. Unsaturated zone map for HUC 031402020803, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin exhibits a favorable soil storage capacity, ranging between 45 to 60 inches of remaining capacity.

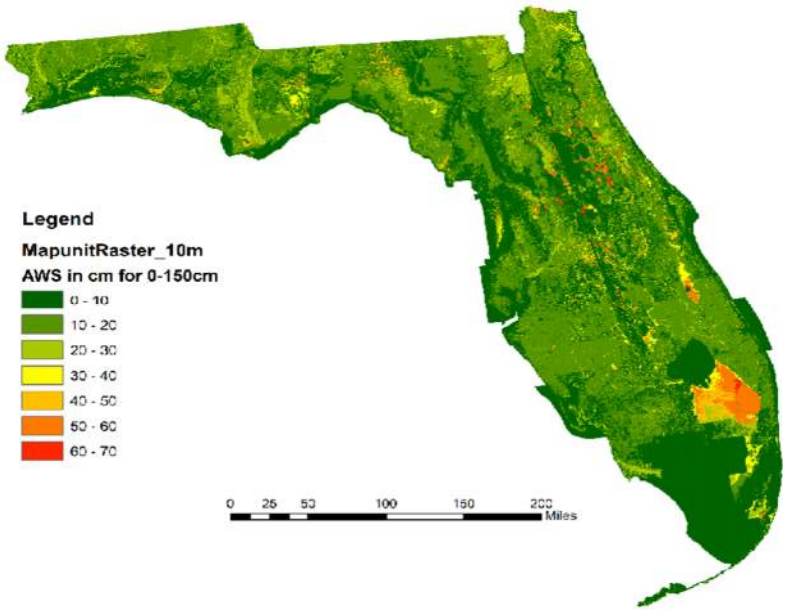

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

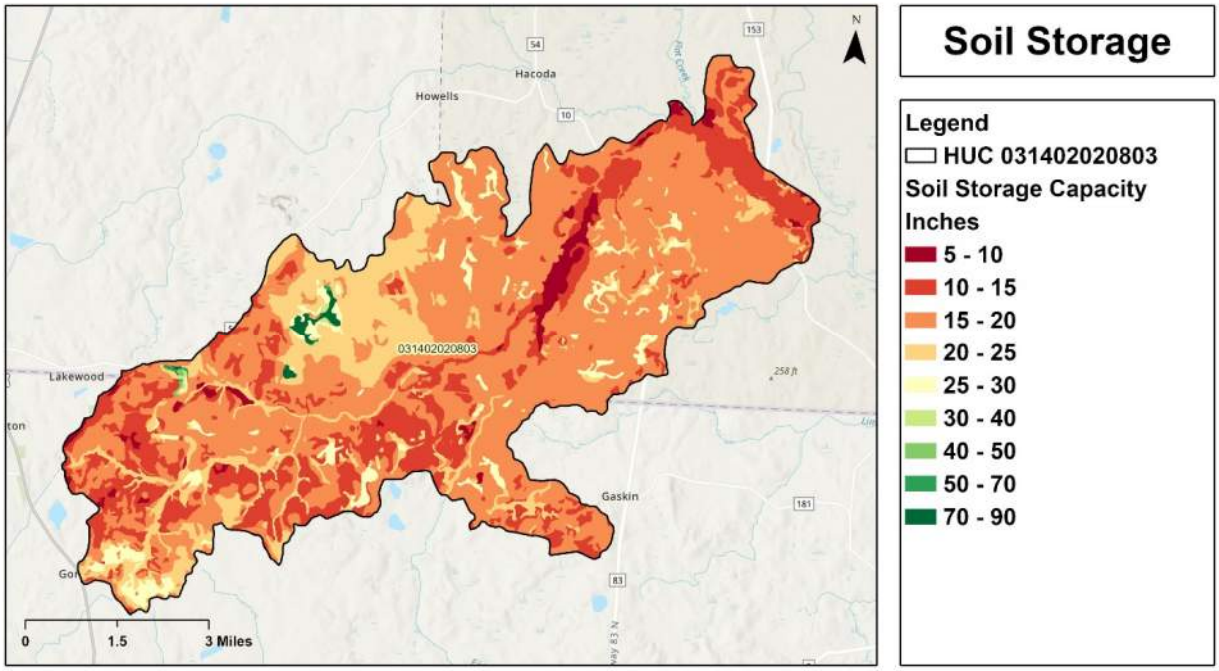

Figure 17. Water storage capacity of soil for the HUC 031402020803, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

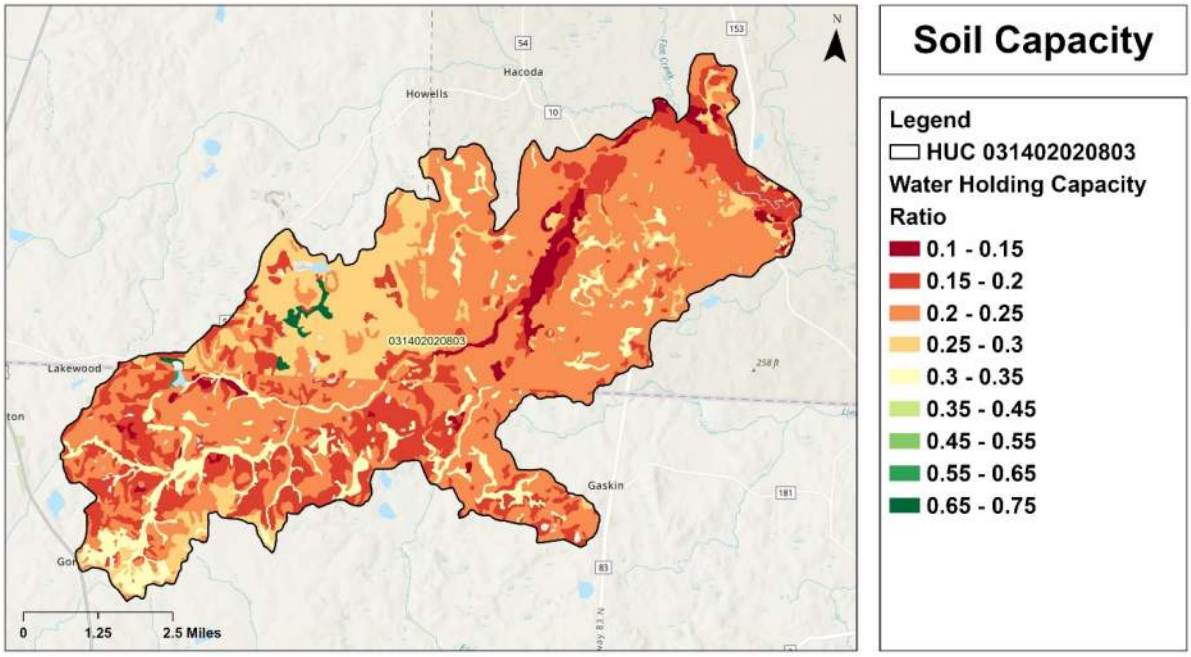

Figure 18. Water Holding Capacity (ratio) for the HUC 031402020803, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

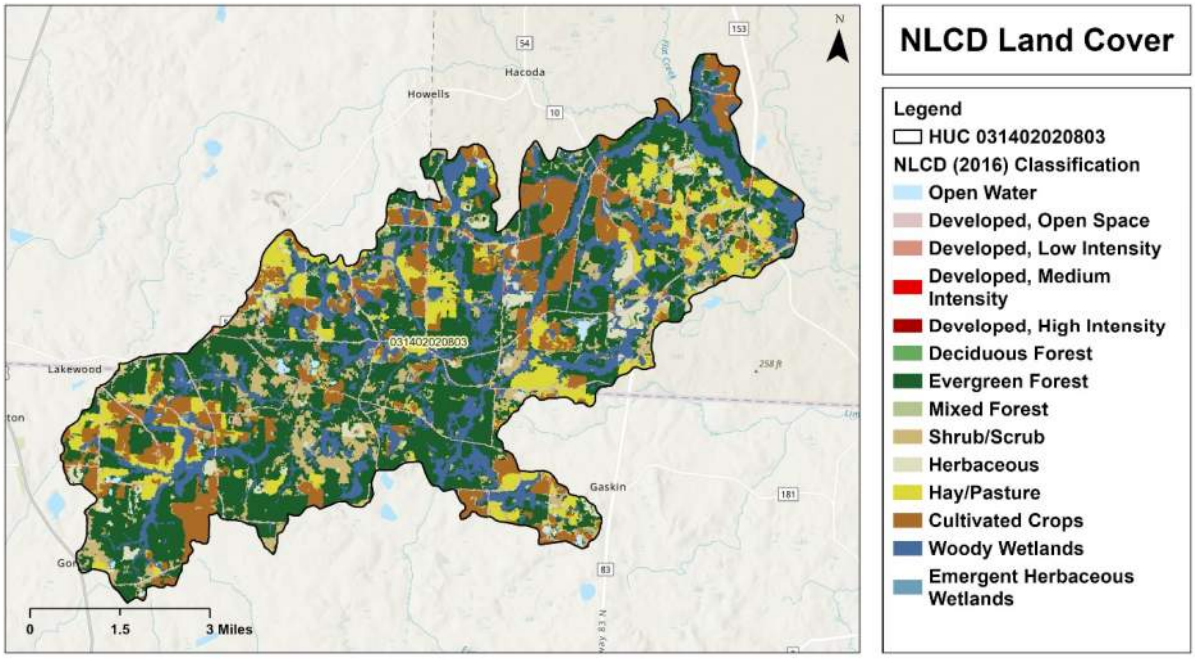

Figure 19. Land use in the HUC 031402020803 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD 2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

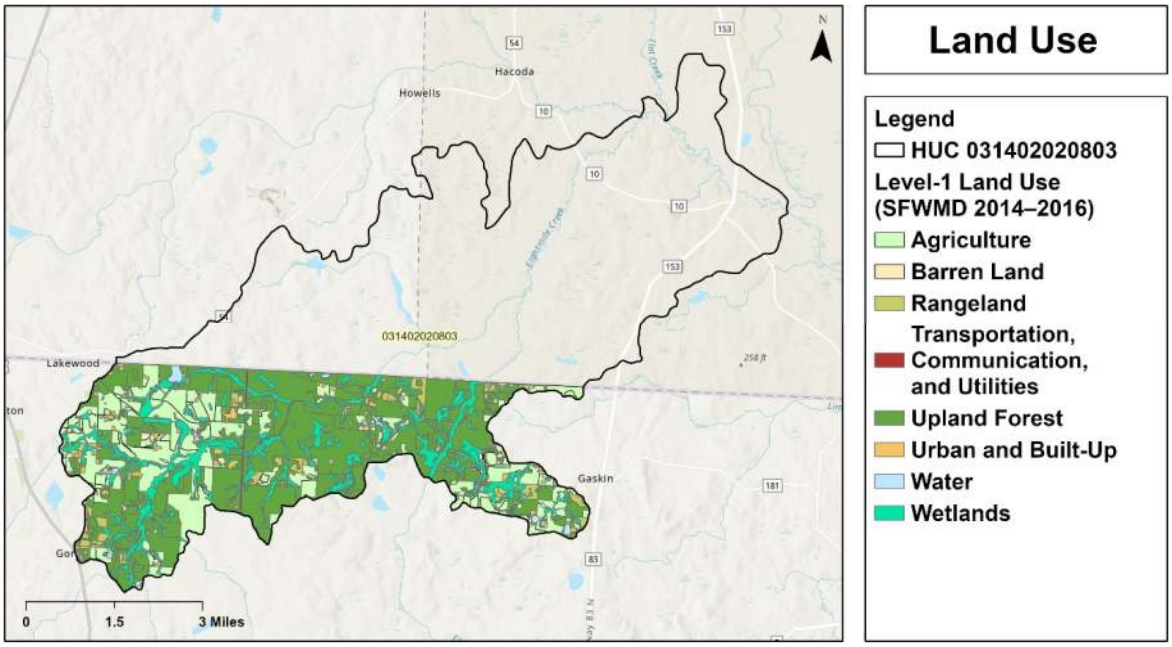

Figure 20. Land use in the HUC 031402020803 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

Please be aware that the Alabama portion of the HUC was not considered in this land use study. Consequently, the following analysis pertains solely to the Florida portion of the HUC 031402020803 sub-watershed. In this area, the predominant land cover is upland forest, accounting for 47.18% of the region. Agriculture comes in second at 30.39%, followed by wetlands at 13.98%. Developed land is limited, with only 2.12% categorized as urban and built-up, as illustrated in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface

Table 3. Land use for HUC 031402020803 subwatershed

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	4666.67	30.39%

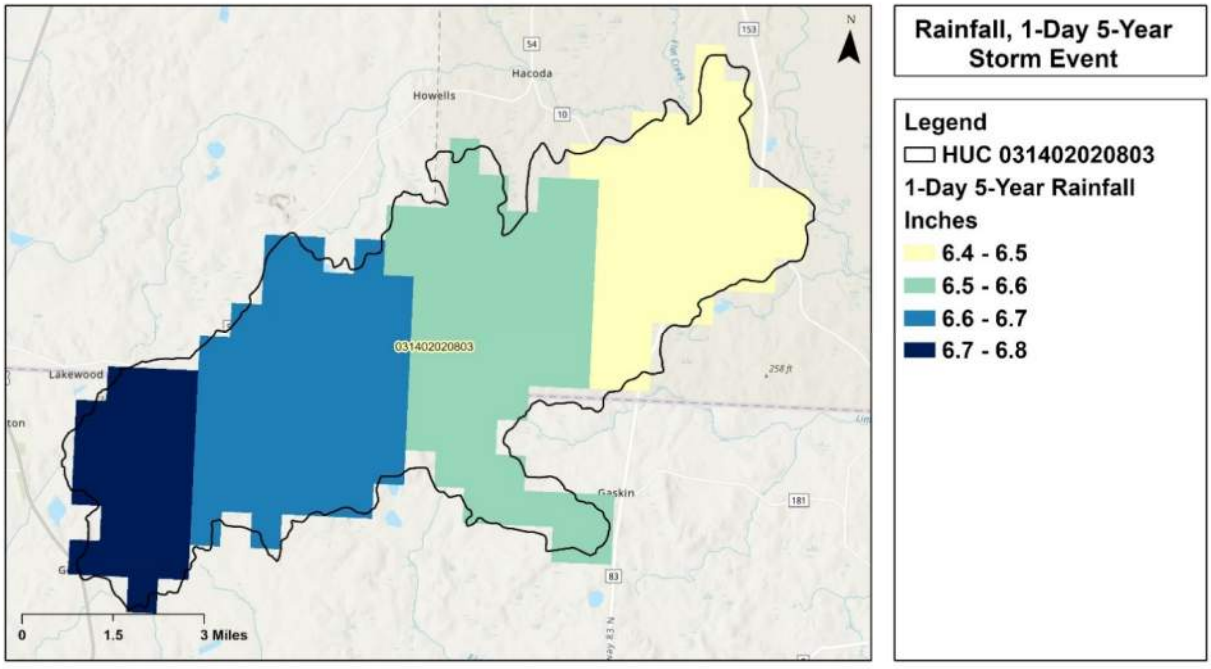

Figure 24. Rainfall distribution map across HUC 031402020803 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

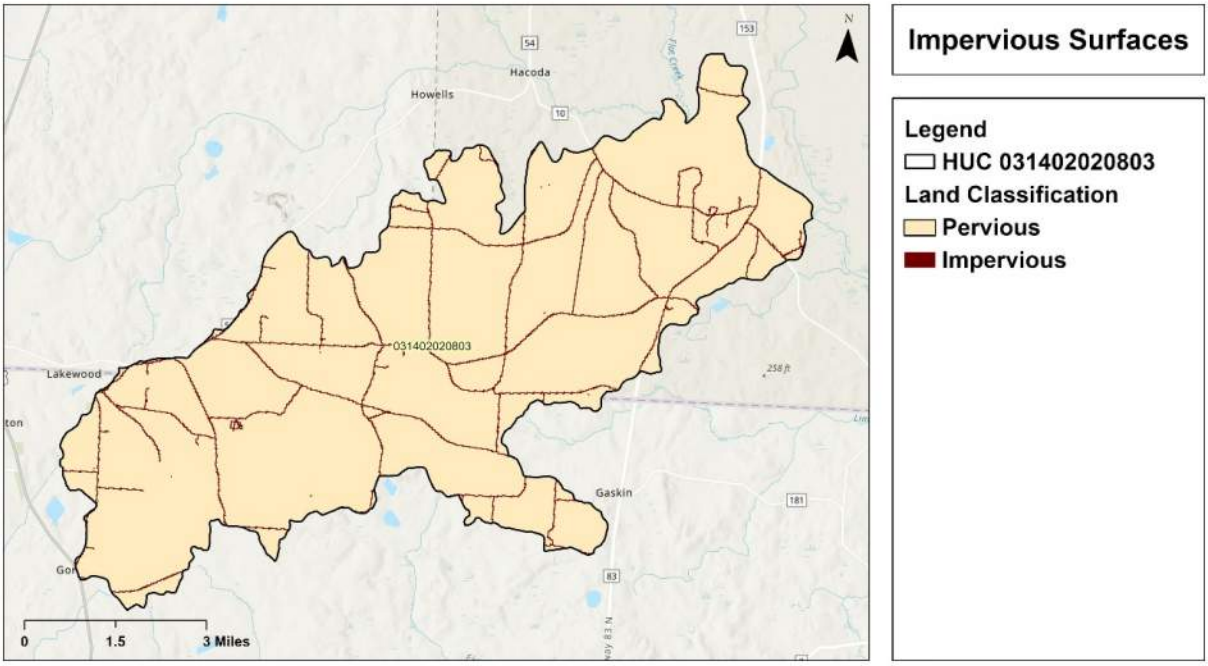

Figure 25. Impervious area map for the HUC 031402020803 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

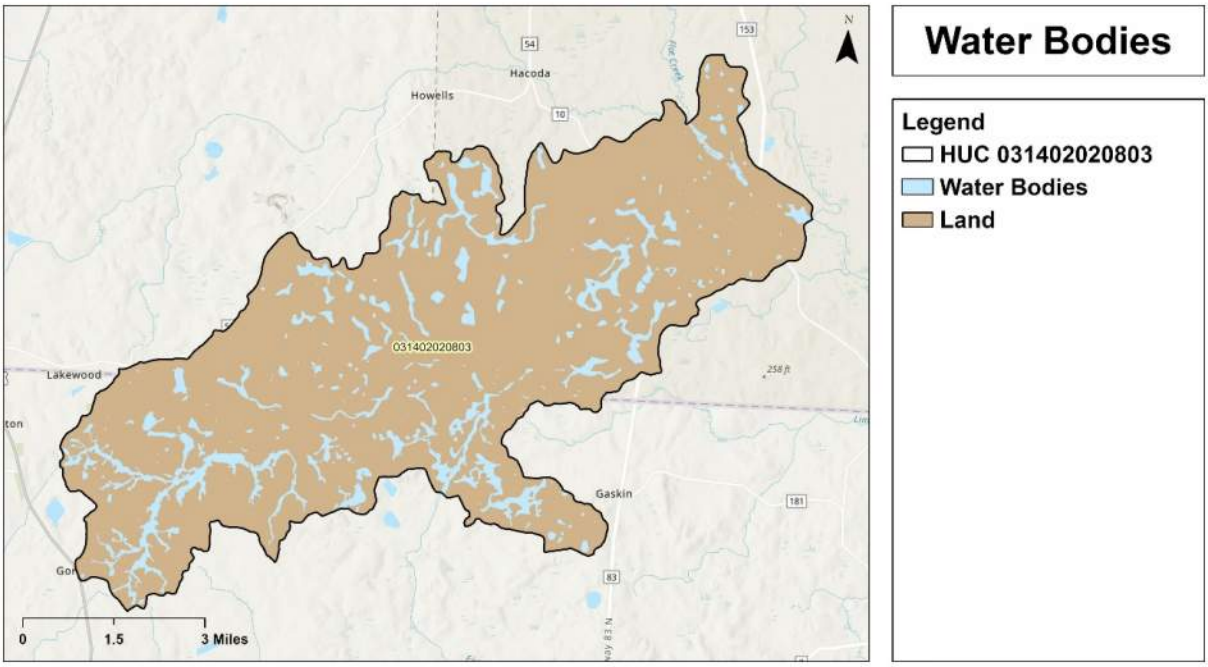

Figure 26. Water bodies map for the HUC 031402020803 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.

- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

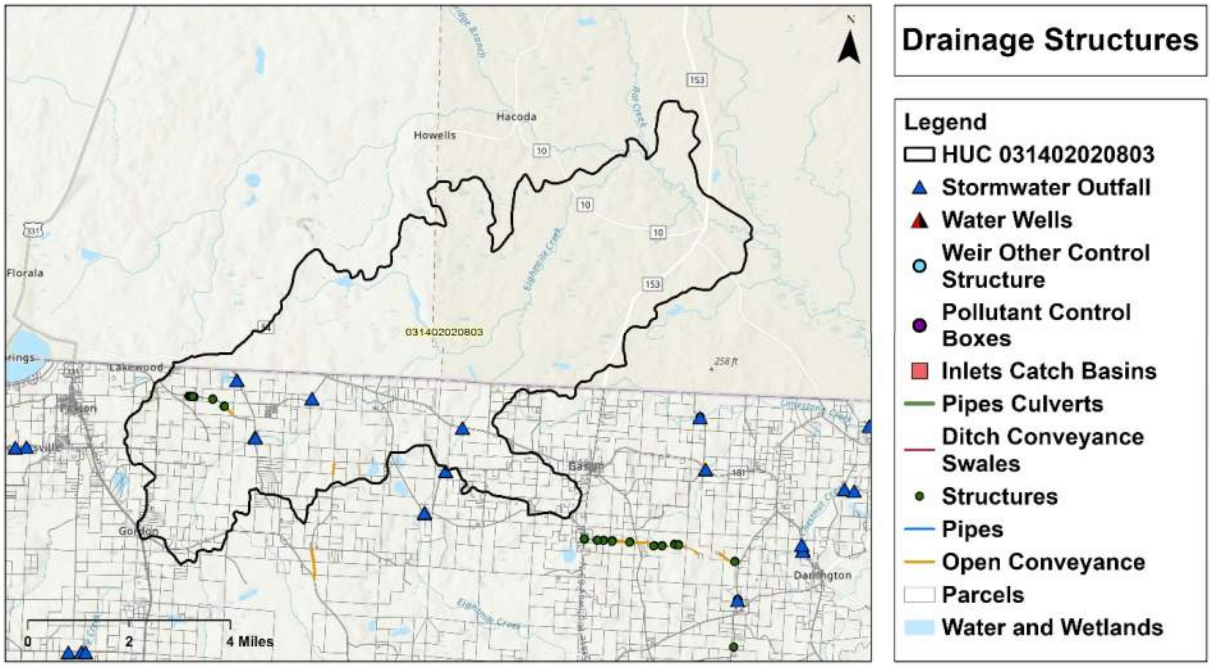

Figure 27. Stormwater Infrastructure for the HUC 031402020803. Processed by FAU.

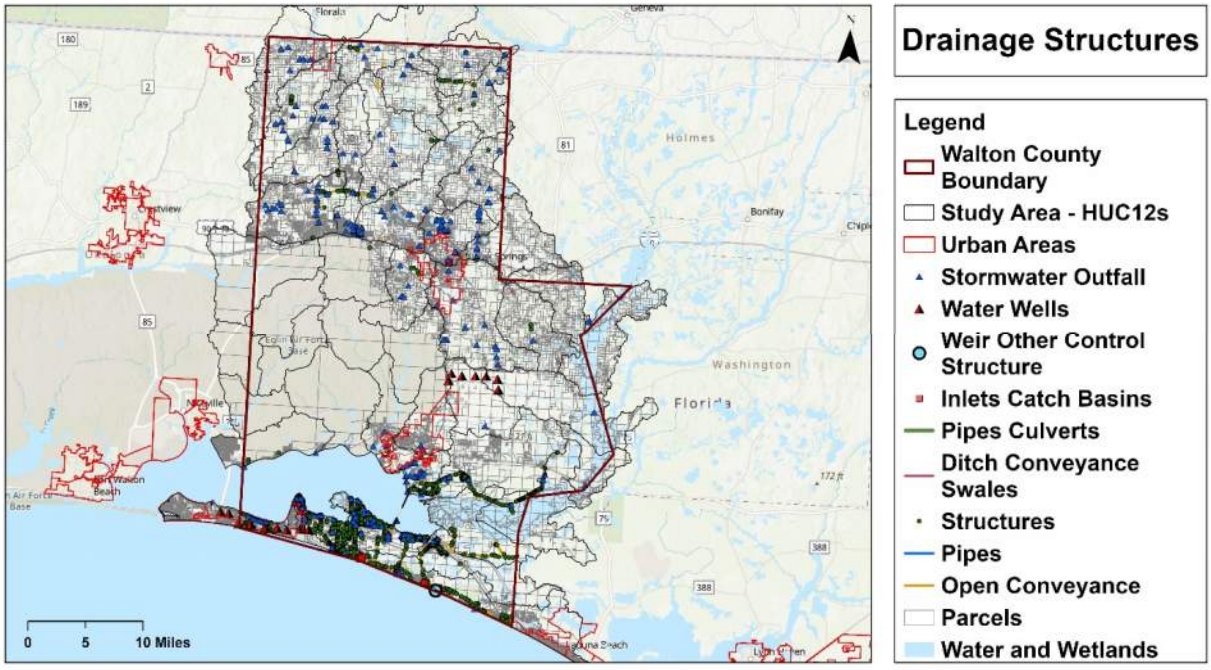

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

Data Category	Dataset Name	Original Source	Spatial Coverage/ Resolution	Temporal Coverage/ Resolution	Link to the Dataset on our Server (physical location)	Dataset size and Format	Native or FAU Processed dataset

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapter 1, an analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031402020803 sub-watershed flood response to a series of rainfall events (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.3.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

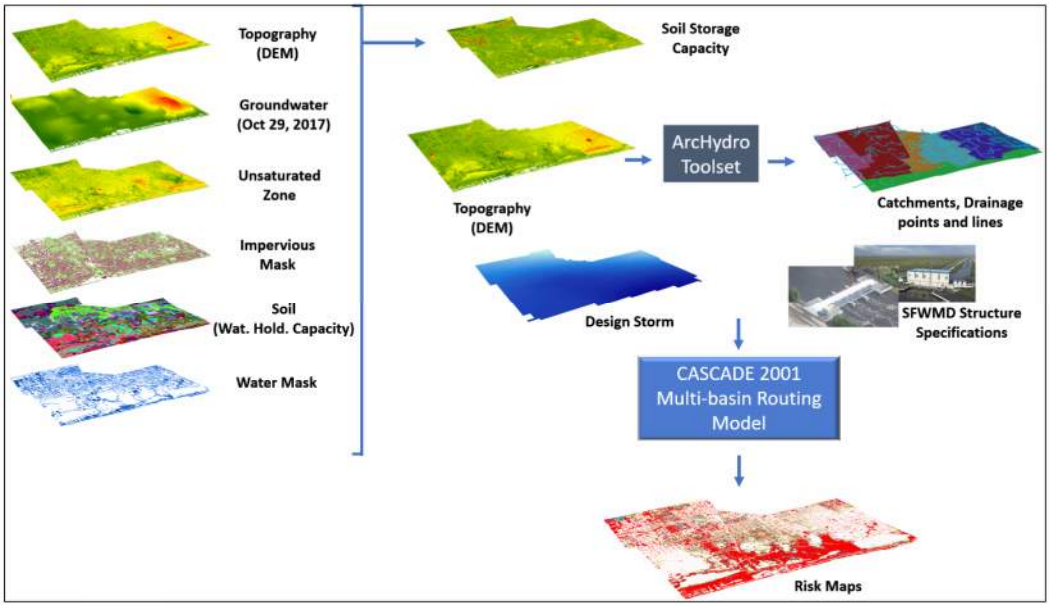

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)

= 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

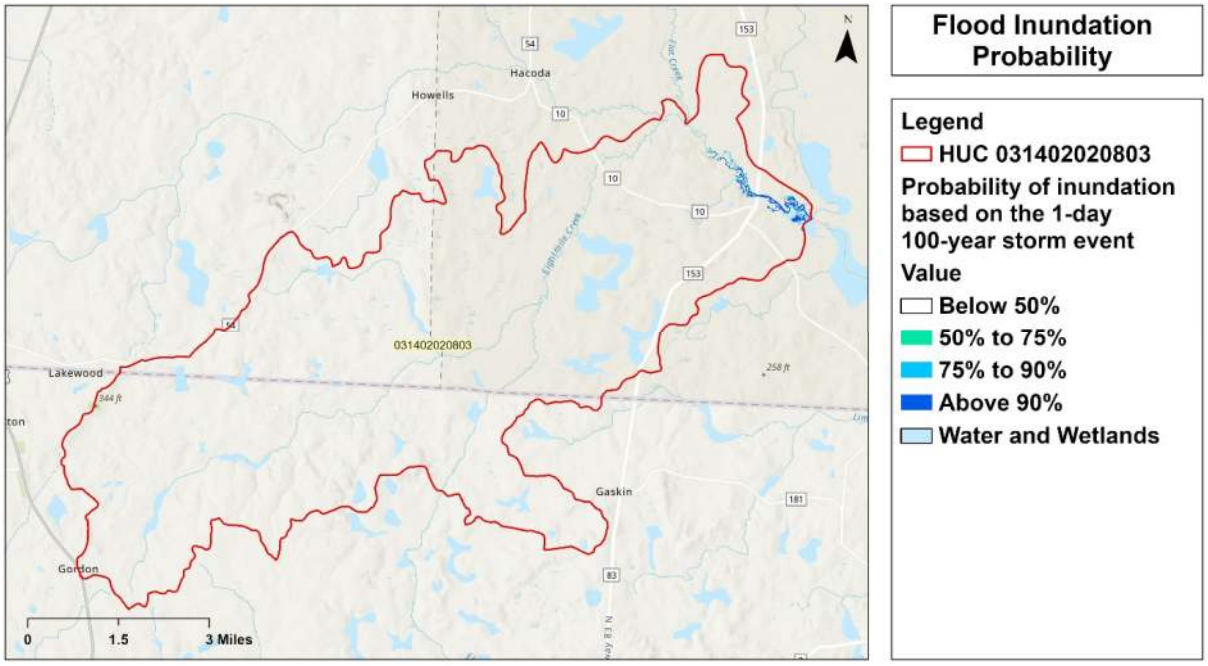

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031402020803, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation

and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 2.4 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations,

Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding is noted at the creek entrance to the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 0.38% of the HUC total area or 0.183 mi² has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.32% of the HUC's total area, or 0.153 mi² would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.23% of the HUC's total area, or 0.111 mi², would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.22% of the HUC's total area, or 0.104 mi², would be expected to be inundated

during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 03140102020803 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	48.050	0.183	99.62%	0.38%
1-day 100-year	48.081	0.153	99.68%	0.32%
1-day 10-year	48.123	0.111	99.77%	0.23%
1-day 5-year	48.130	0.104	99.78%	0.22%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6

101	Parcels With no Values (ROW - avenues, highways, arterials)	2
102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031402020803 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (Figure 35) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 36) overlays critical facilities onto the 1-day

100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

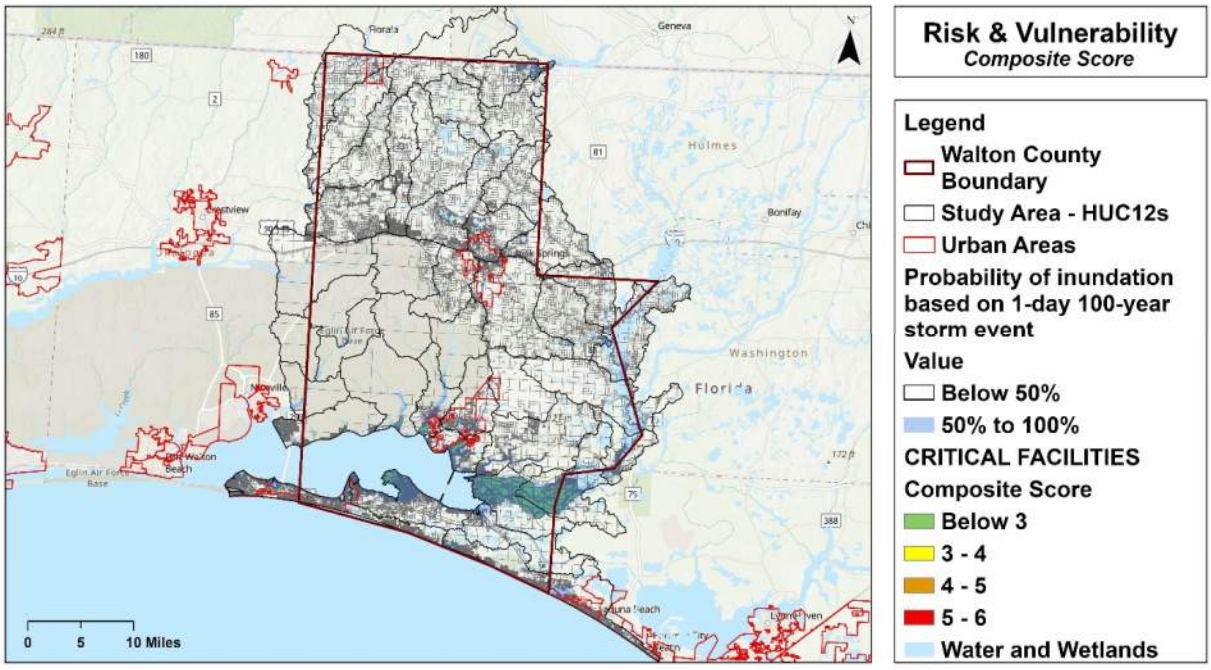

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031402020803. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031402020803. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031402020803	30870.63
All of the 1-day 100-year storm event inundation	**97.63**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	97.63
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	97.63

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

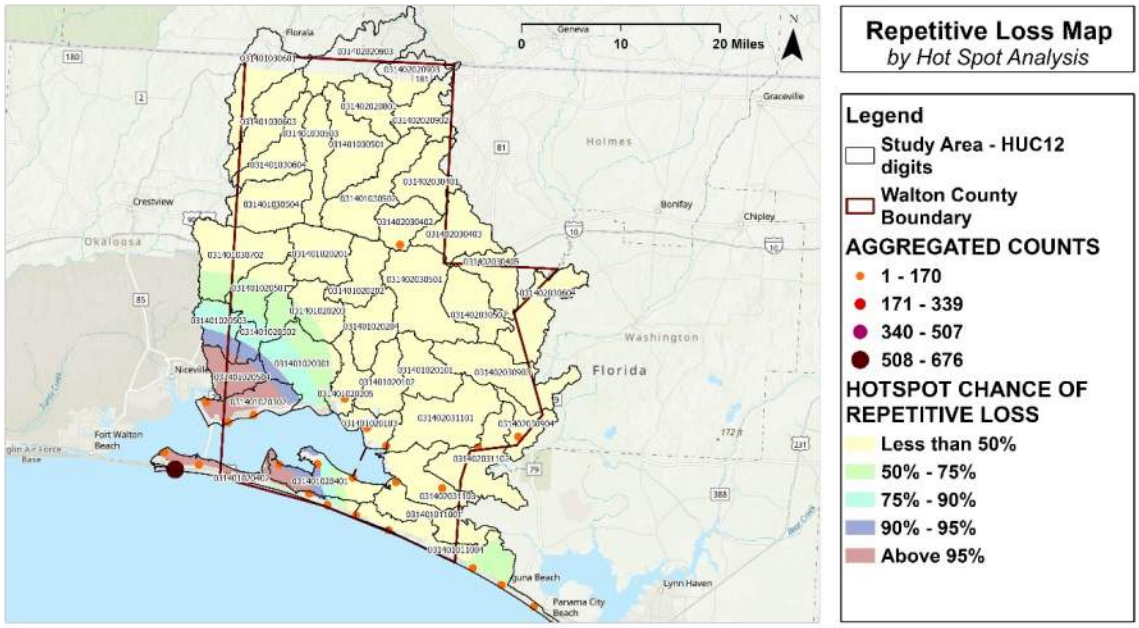

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are a few parcels falling within classification tier 4 and 5 of priority of land uses, none of them are within the flooding zone, which is outside Florida's boundary. Consequently, when considering the composite score, it is notable that the results are null, indicating no priority for intervention within the Florida's side of the basin.

It is also important to mention that a good portion of the basin has not been included in the priority land use analysis and, consequently, in the composite score calculation. This omission is due to the project's reliance on land use data solely from Florida, and the basin has a portion on Alabama as well. The categories of land use maps in Alabama would be different, making it impossible to match the data from two different databases in different states. As a result, there is a slight

possibility that there may be priority projects on the Alabama side of the basin of which we are not aware.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 (031402020902) is highlighted among all the HUCs to help identifying its location. (Figure 3).

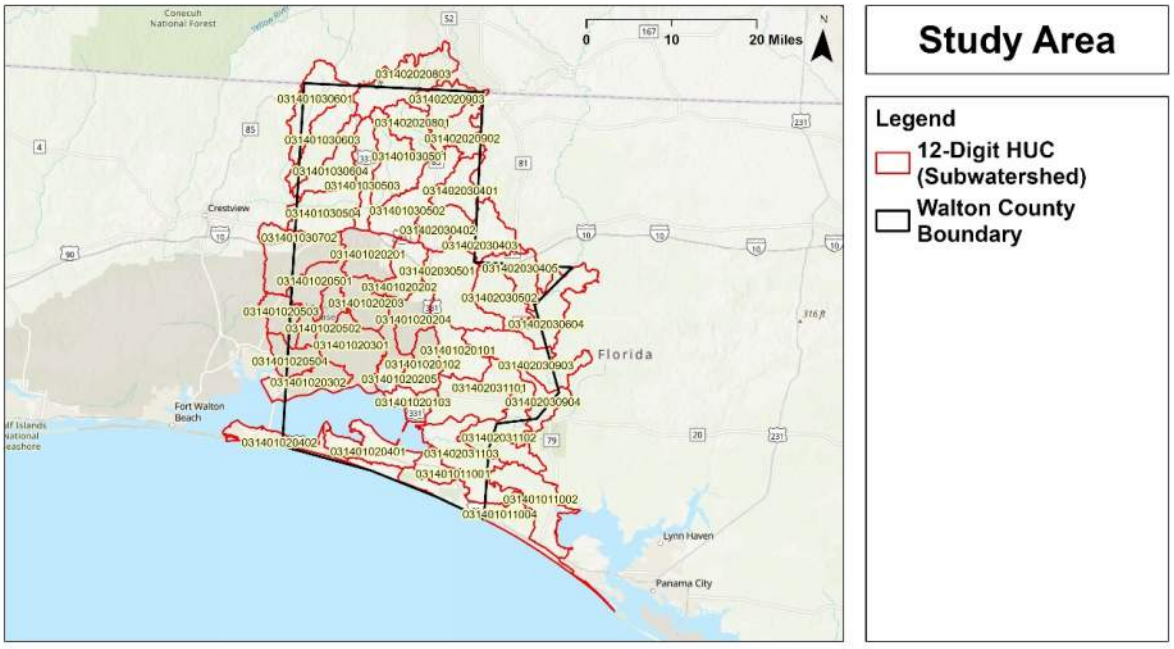

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

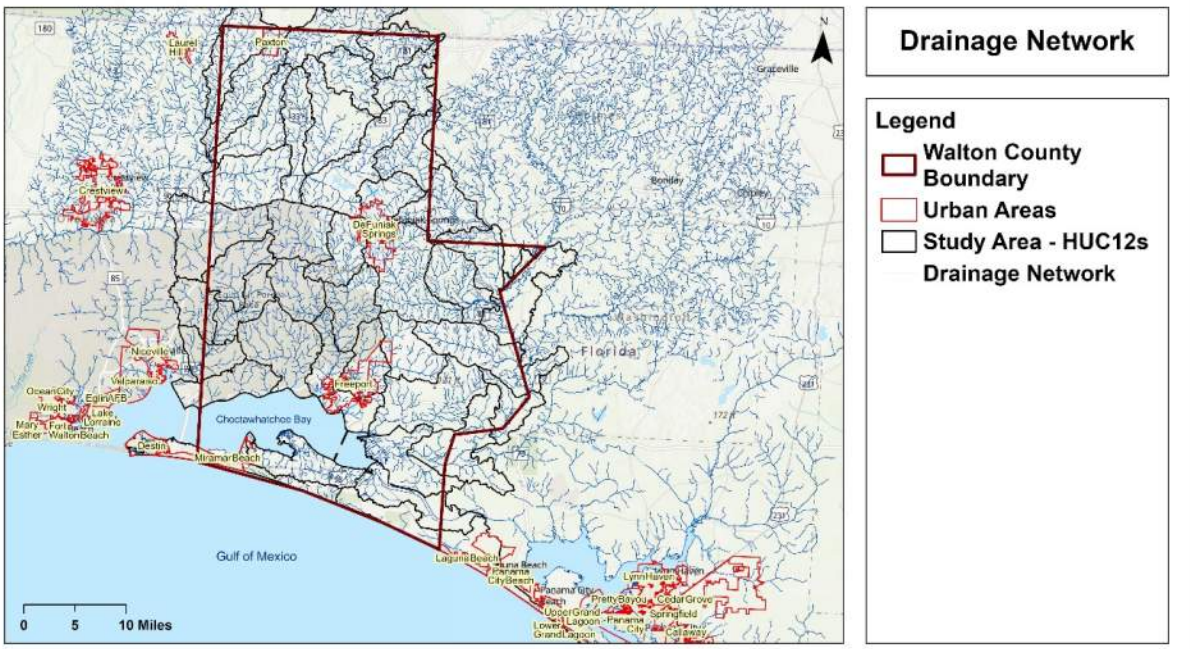

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

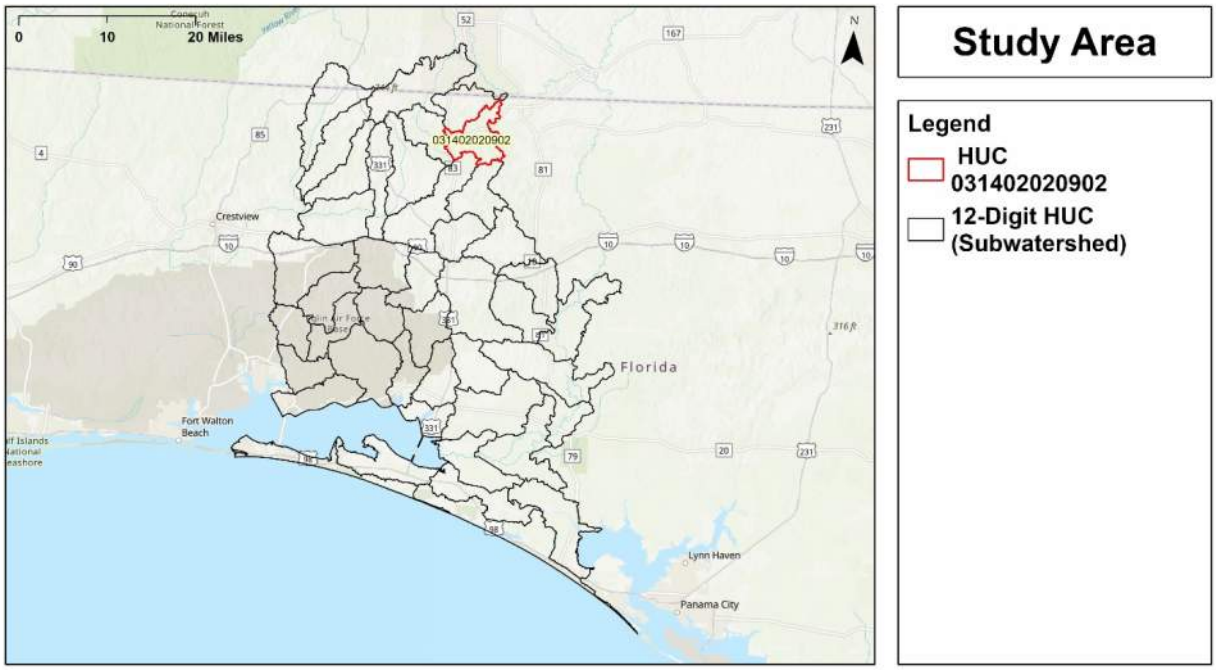

Figure 3. HUC 031402020902 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed i in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

(Source Data: FEMA)

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

(Source Data: NWFWMD, 2017)

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.

April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads. Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

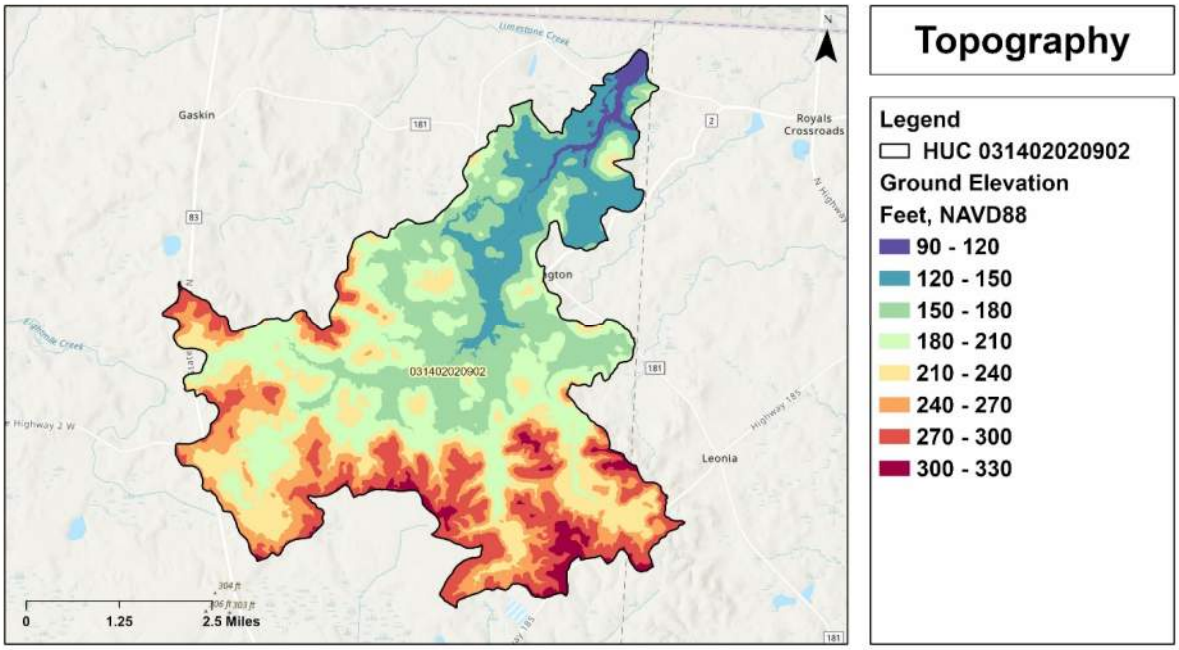

Figure 4. Topographic map of the HUC 031402020902 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031402020902 sub-watershed is shown in Figure 5.

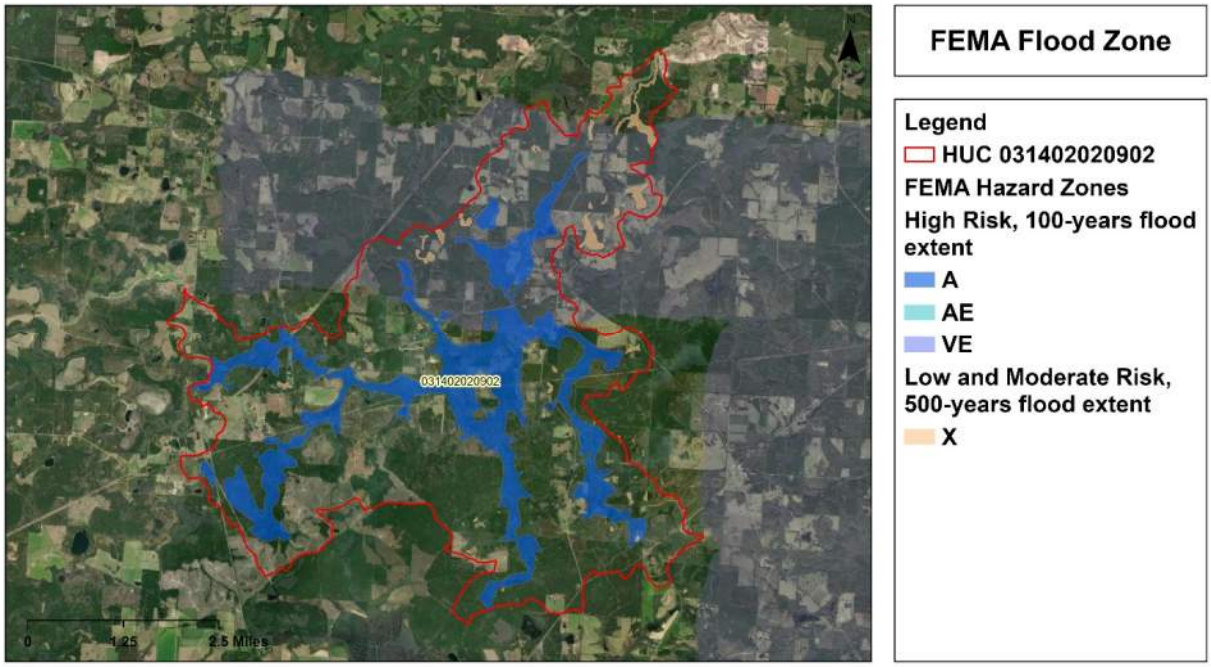

Figure 5. FEMA Flood Zone map (2020) for HUC 031402020902 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031402020902 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including

various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

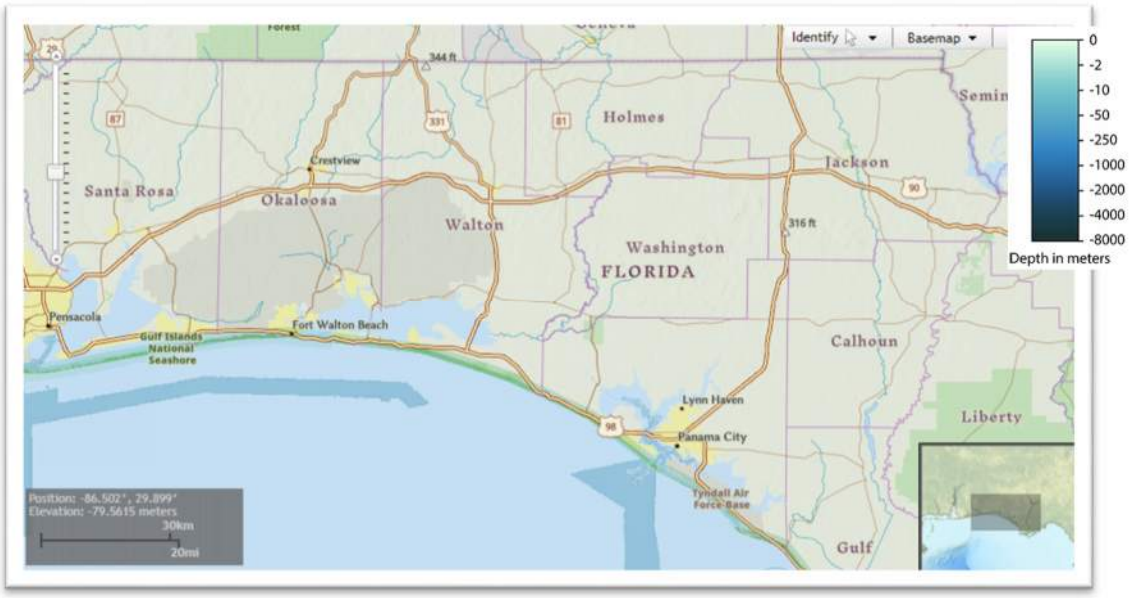

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle. Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

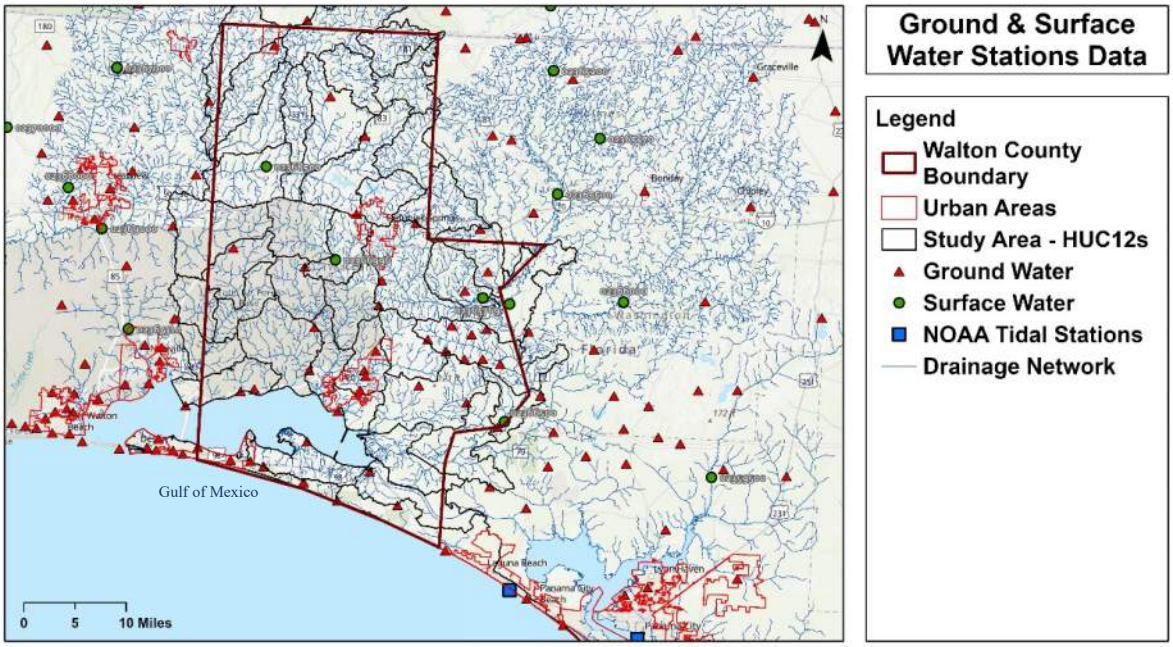

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031402020902 lacks major rivers and canals, instead featuring a network of well-branched creeks without specific names. These creeks originate in Alabama and flow in different directions though the basin.

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031402020902, which is USGS 02368500 Shoal River.

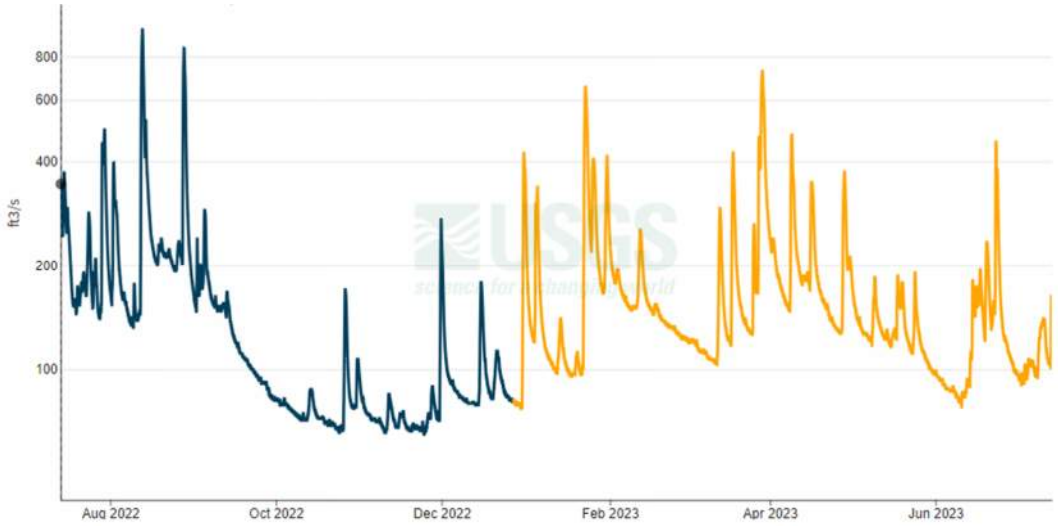

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data is obtained from the SFWMD DBHYDRO site for surface waters (https://www.sfwmd.gov/science-data/dbhydro) and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031402020902 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031402020902 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

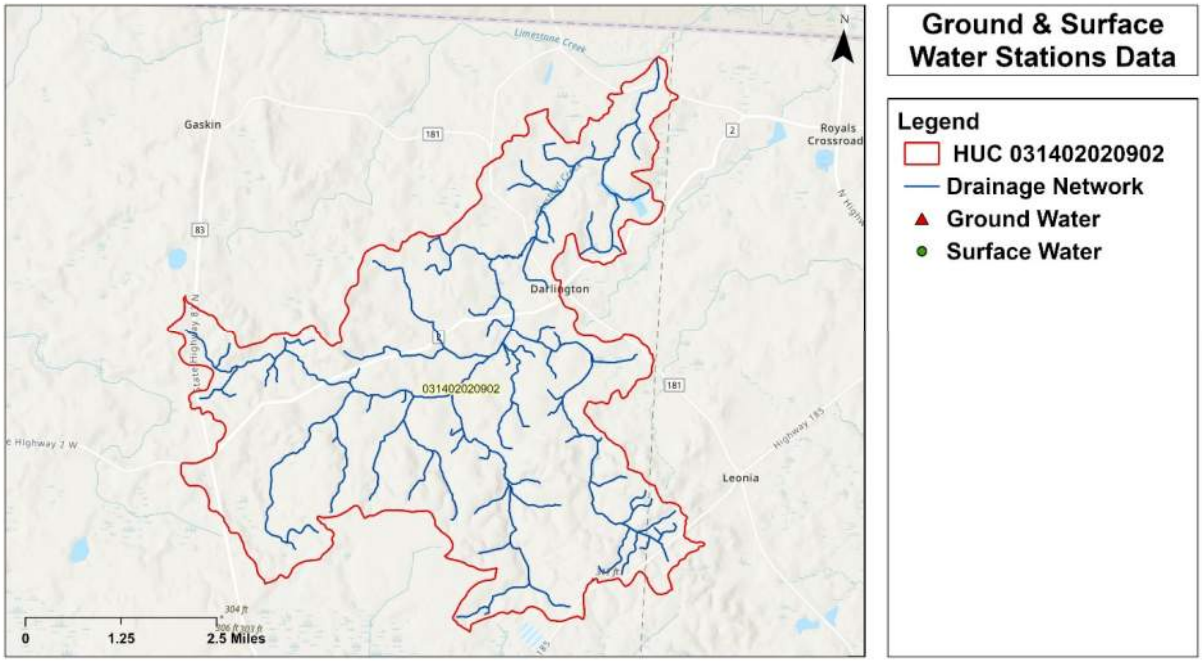

Figure 9. Ground and Surface Water Stations in the HUC 031402020902 sub-watershed, processed by FAU.

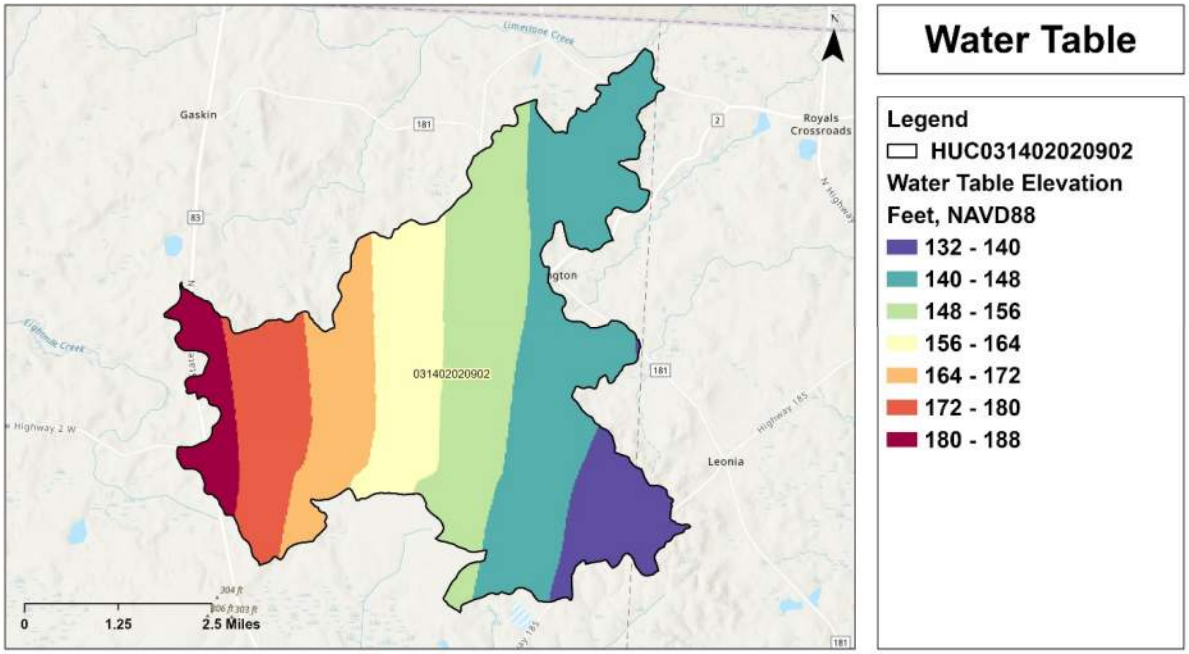

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031402020902 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the average precipitation over Walton County for every month of the year between 2011 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches for the entire county.

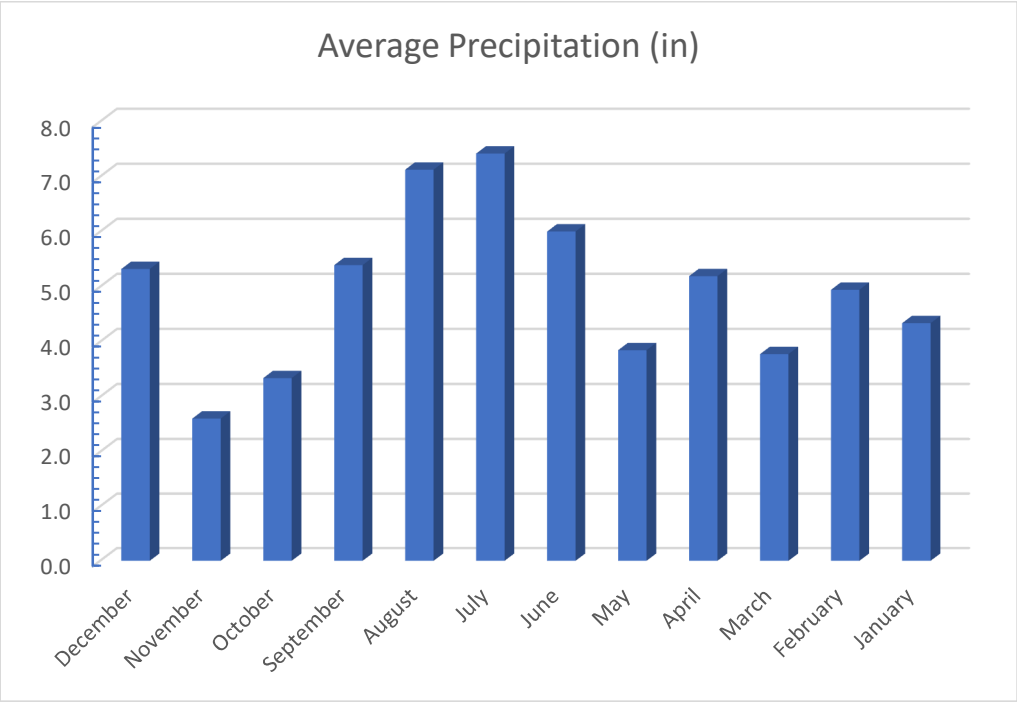

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4)create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as

opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. Figure 12 shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

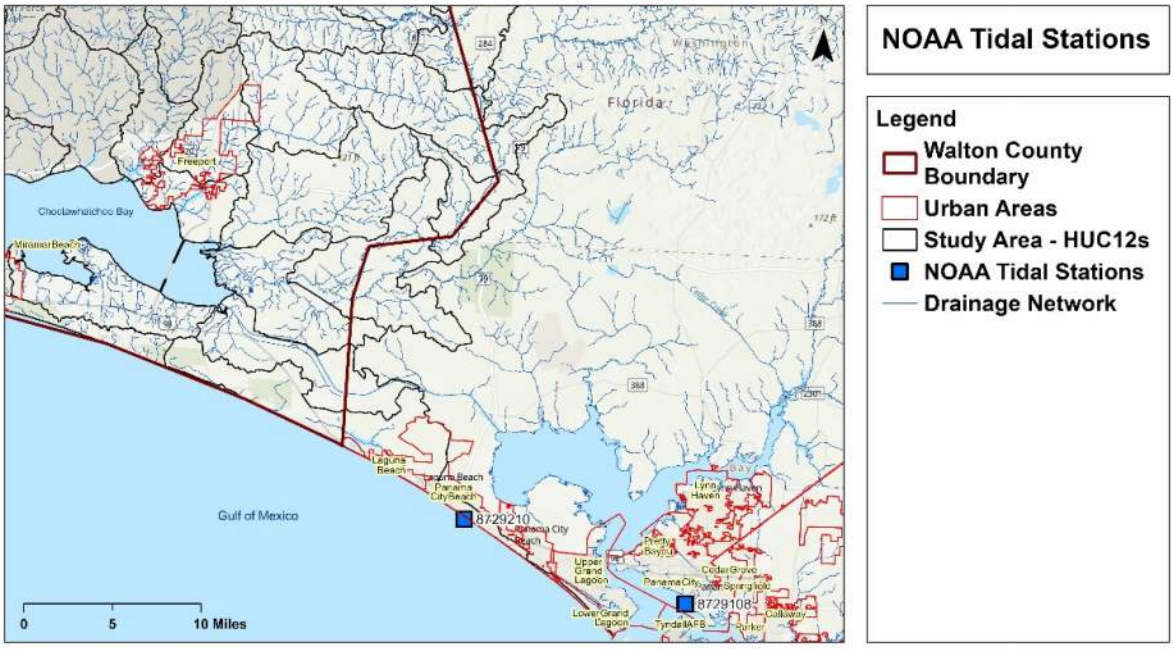

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

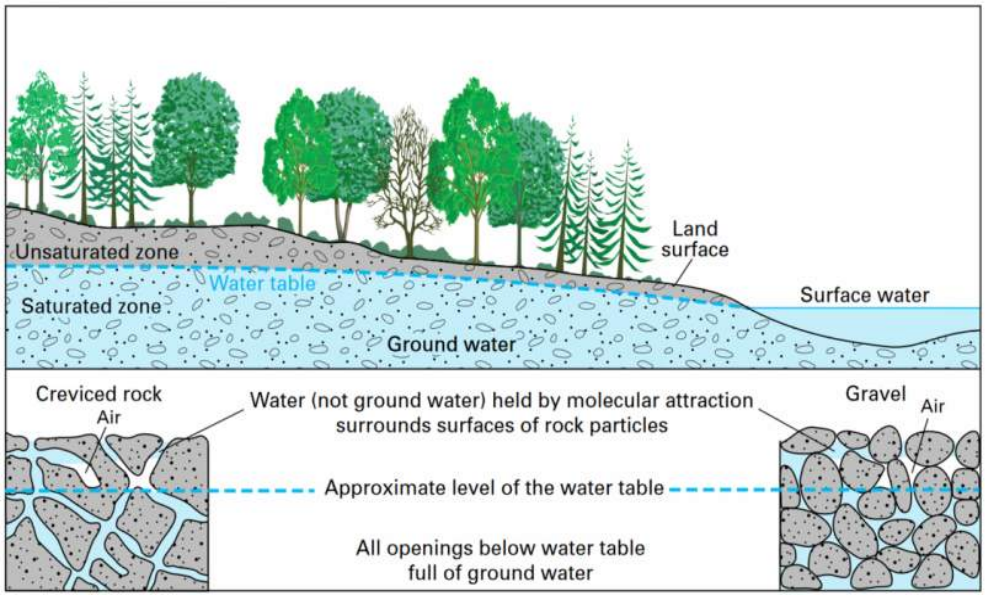

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in Figure 14. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

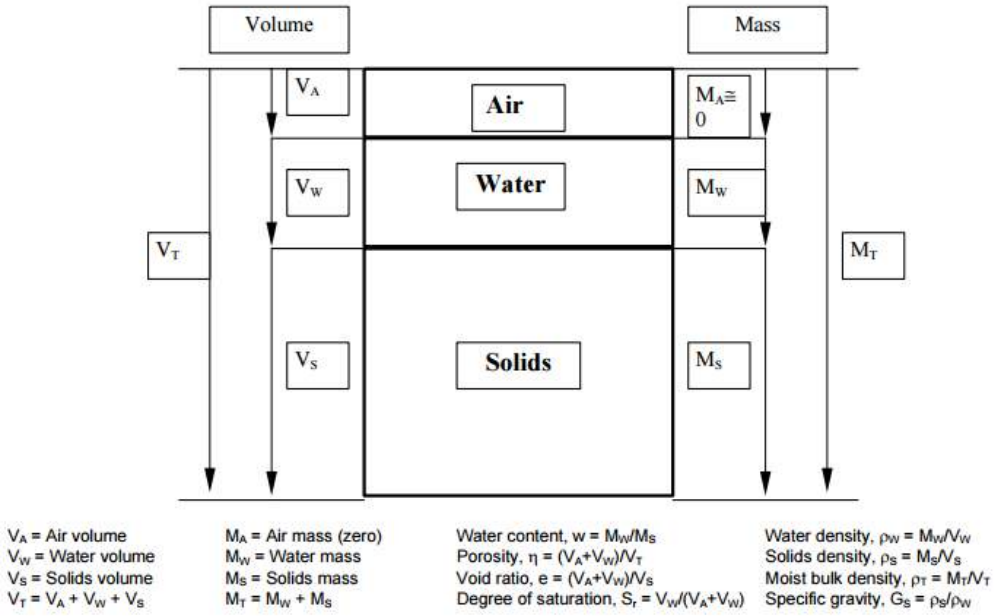

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

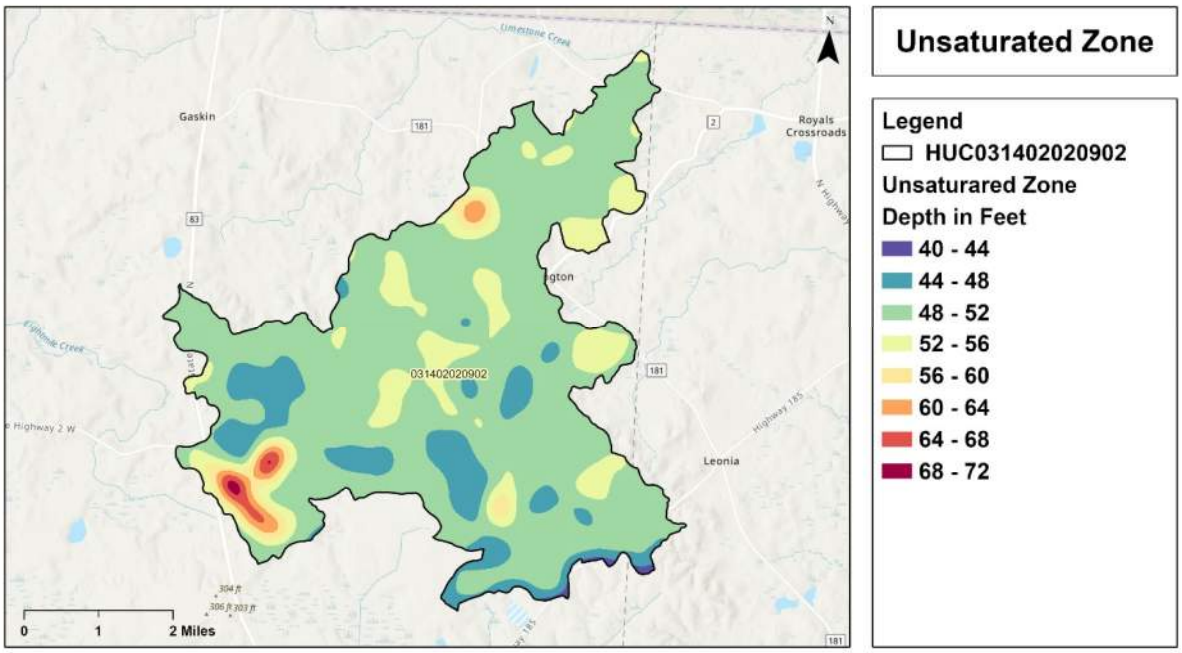

Figure 15. Unsaturated zone map for HUC 031402020902, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. The entire basin exhibits a favorable soil storage capacity, ranging between 40 to 72 inches of remaining capacity.

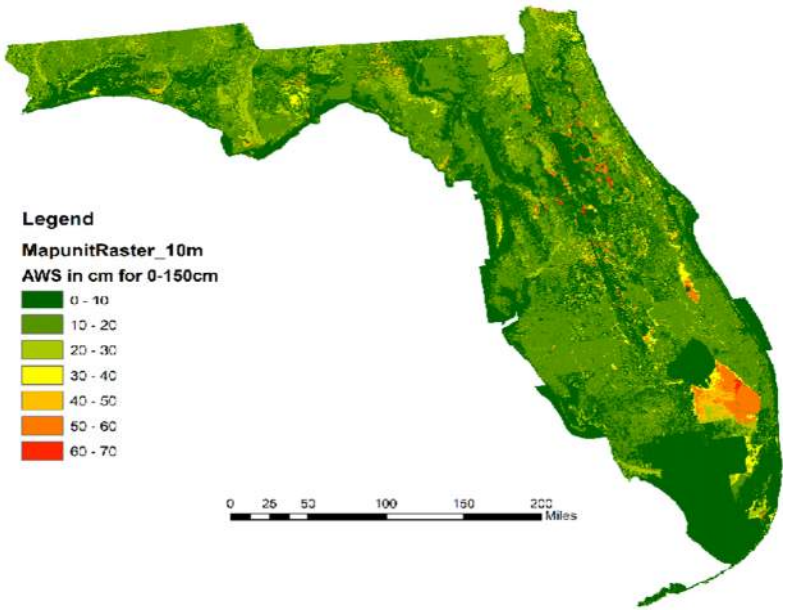

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

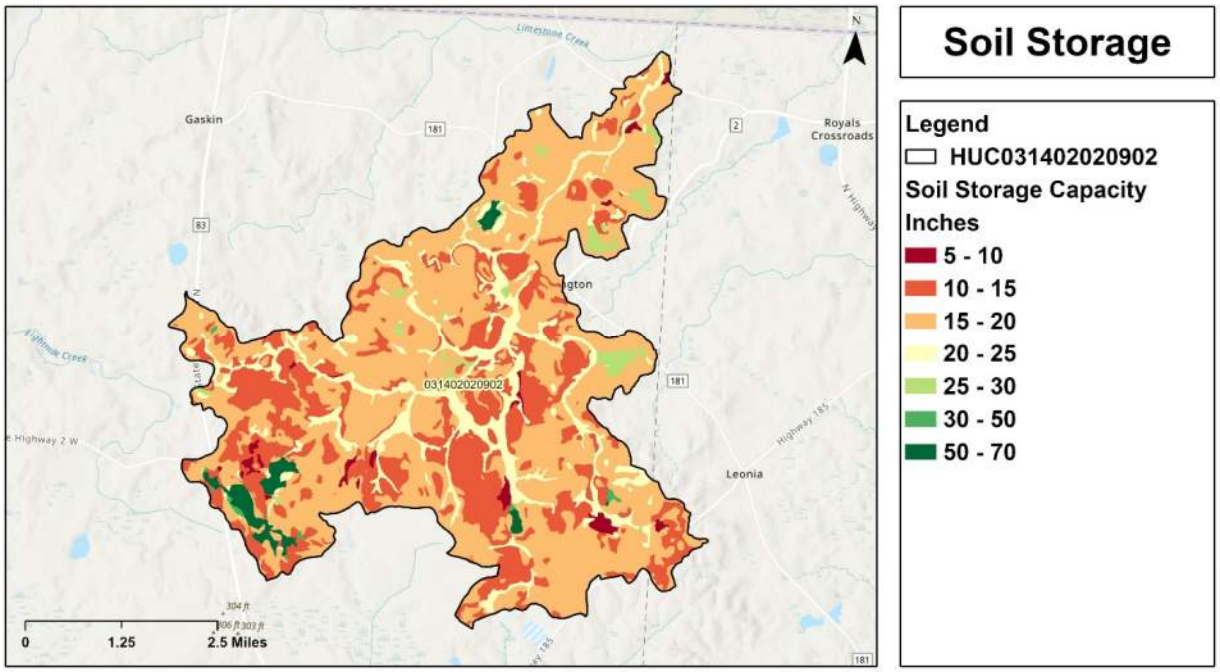

Figure 17. Water storage capacity of soil for the HUC 031402020902, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

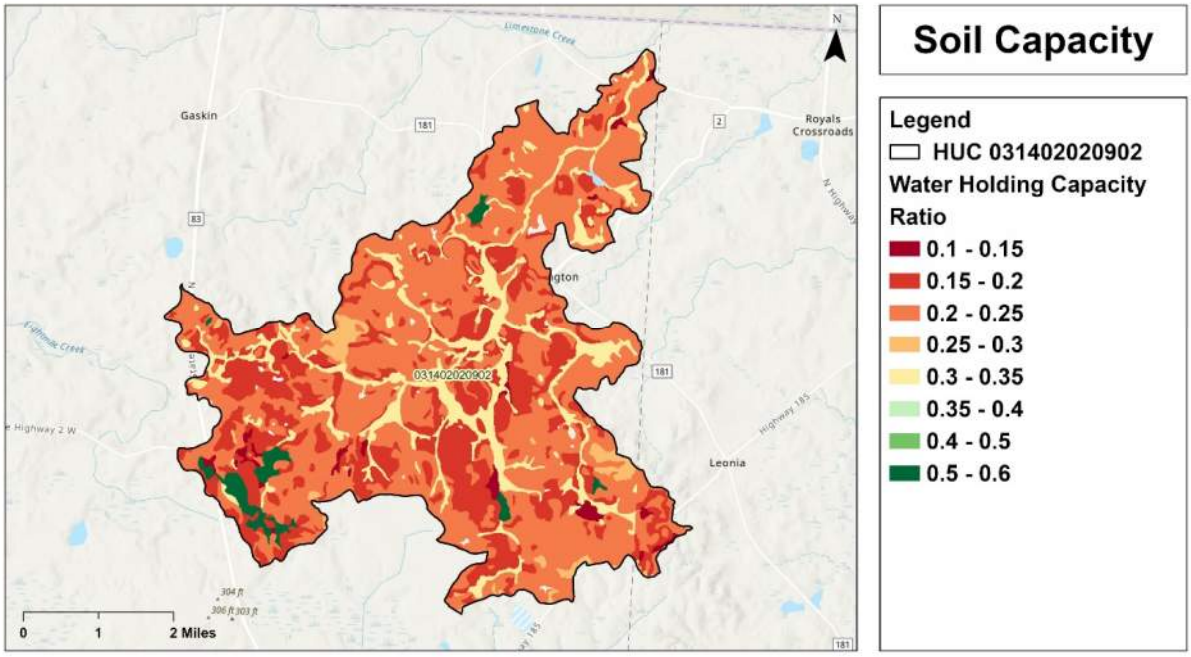

Figure 18.Water Holding Capacity (ratio) for the HUC 031402020902, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

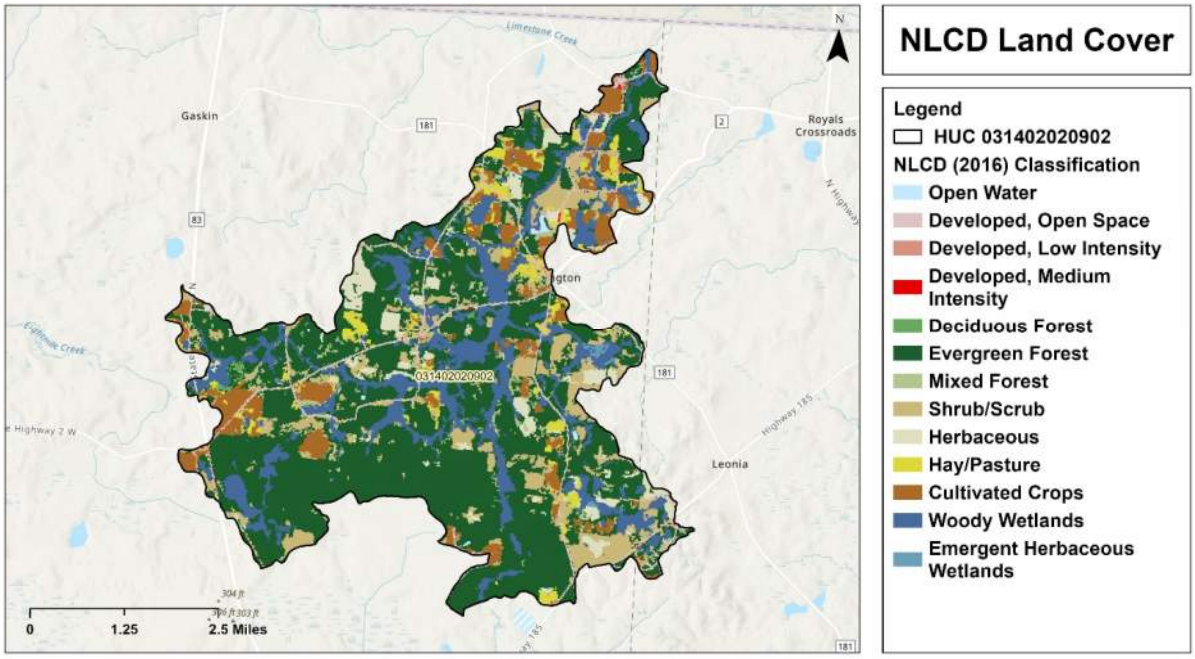

Figure 19. Land use in the HUC 031402020902 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD 2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

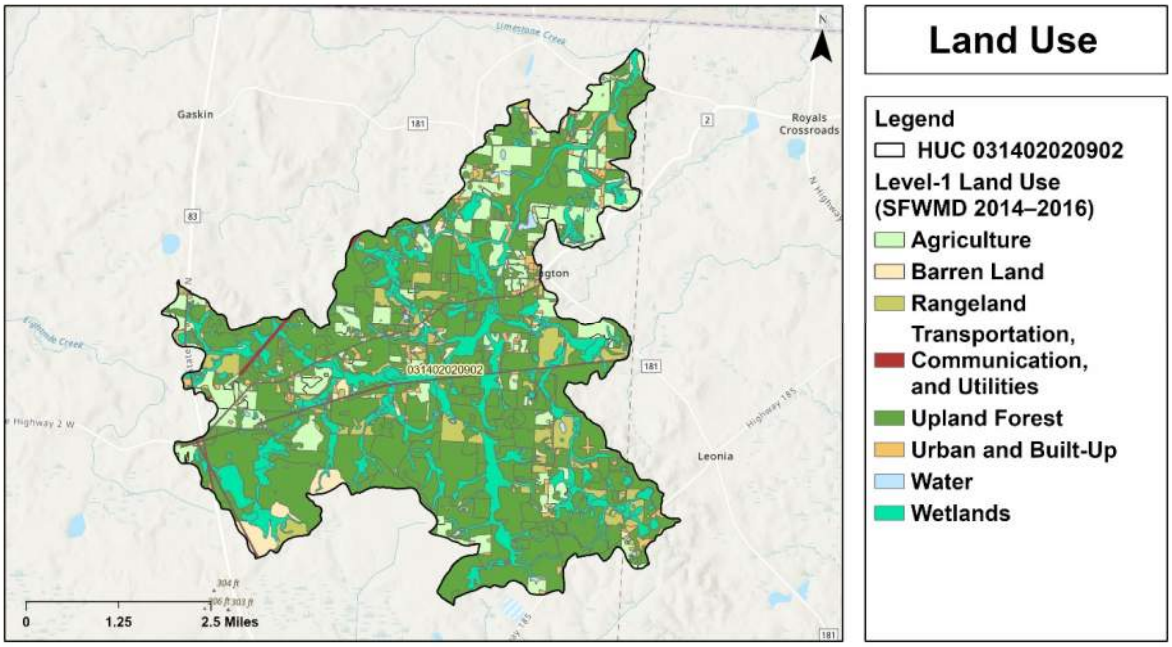

Figure 20. Land use in the HUC 031402020902 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031402020902 sub-watershed, the predominant land cover is upland forest, accounting for 52.93% of the area. Wetlands comes in second at 13.70%, followed by Transportation, Communication, and Utilities at 12.87%, and agriculture at 11.11%. Developed land constitutes a minor portion, with only 1.99% categorized as urban and built-up, as indicated in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031402020902 subwatershed

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	2566.45	11.11%
Barren Land	532.15	2.30%
Rangeland	1081.55	4.68%
Transportation, Communication, and Utilities	2972.31	12.87%
Upland Forest	12227.29	52.93%
Urban and Built-Up	460.71	1.99%
Water	96.64	0.42%
Wetlands	3164.76	13.70%
Grand Total:	**23101.87**	**100.00%**

(Source Data: 2023 Florida Geographic Data Library (FGDL) database))

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

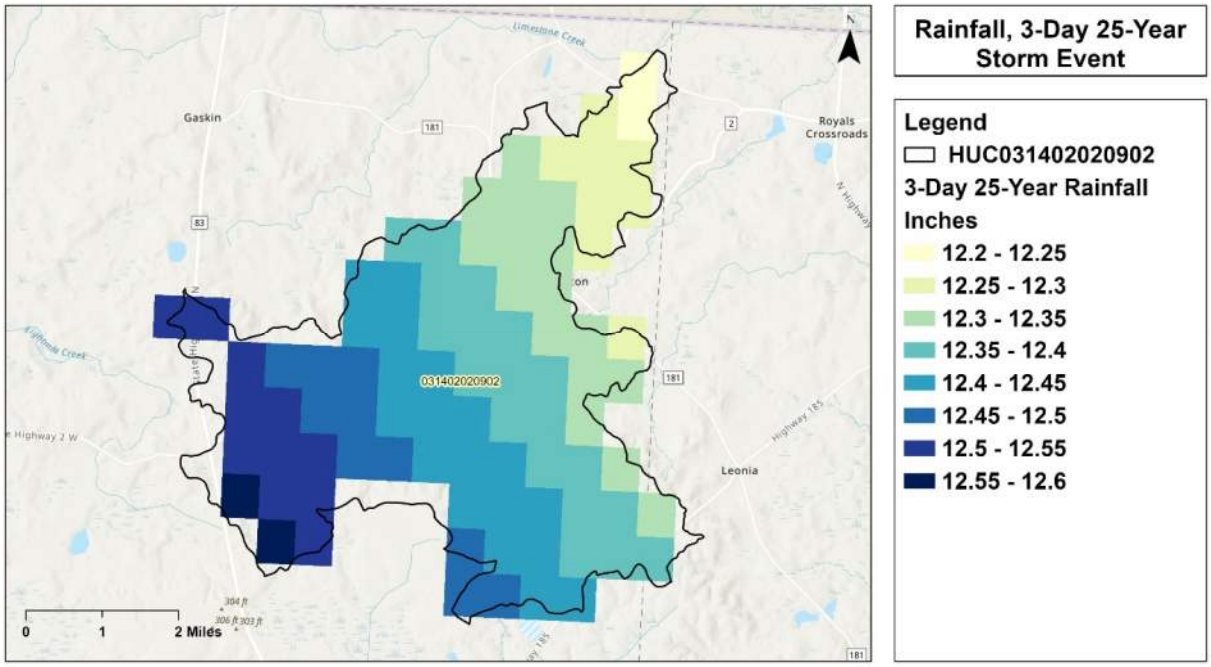

Figure 21. Rainfall distribution map across HUC 031402020902 sub-watershed, for 3-day 25-year storm event, processed by FAU.

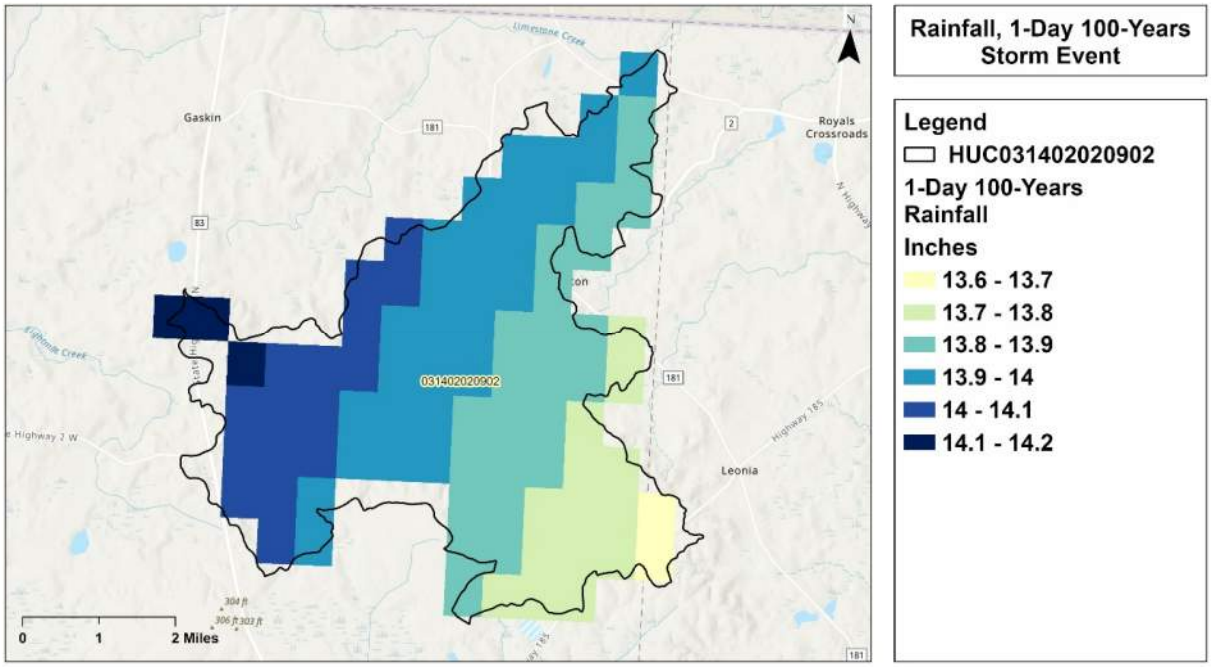

Figure 22. Rainfall distribution map across HUC 031402020902 sub-watershed, for 1-day 100-year storm event, processed by FAU.

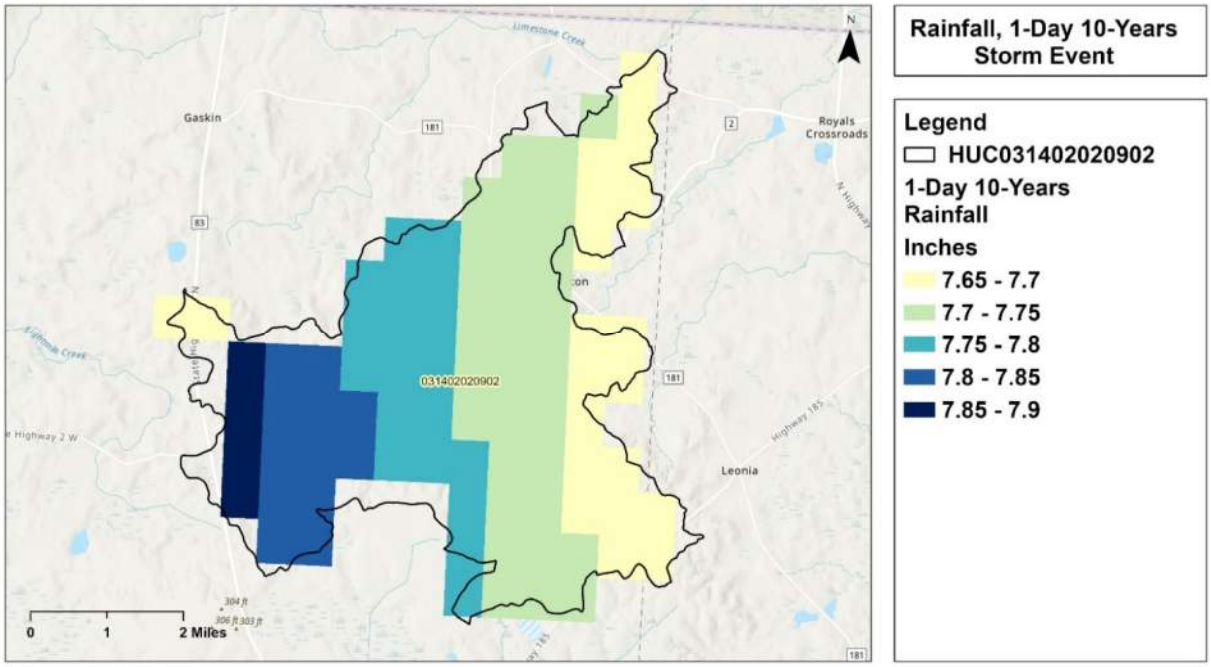

Figure 23. Rainfall distribution map across HUC 031402020902 sub-watershed, for 1-day 10-year storm event, processed by FAU.

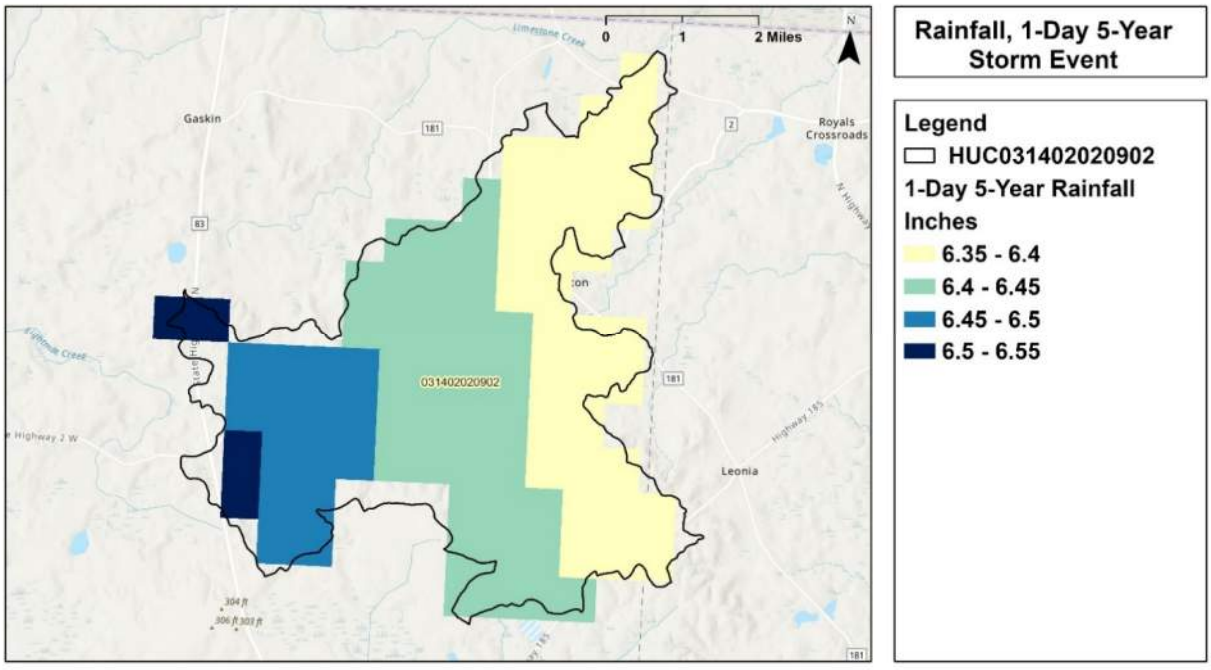

Figure 24. Rainfall distribution map across HUC 031402020902 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

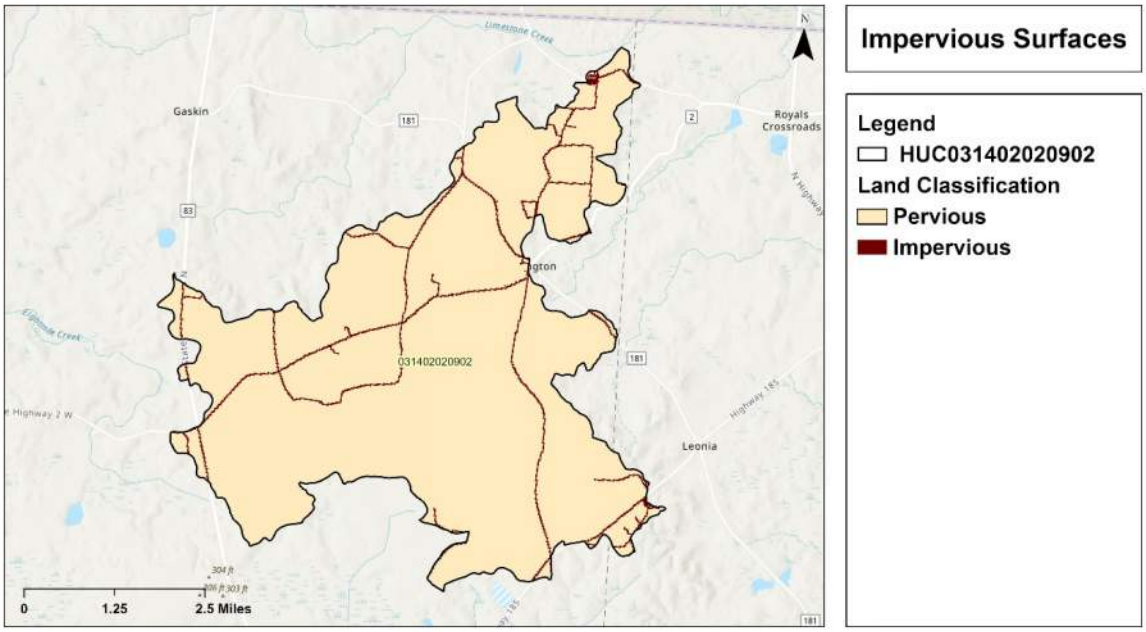

Figure 25. Impervious area map for the HUC 031402020902 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

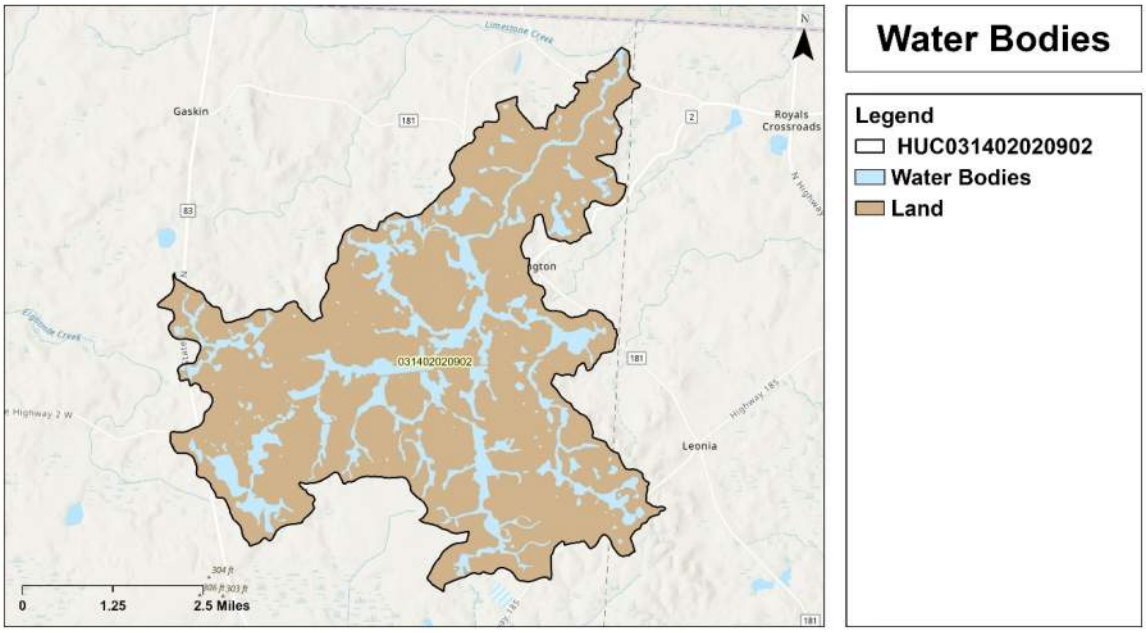

Figure 26. Water bodies map for the HUC 031402020902 sub-watershed, processed by FAU.

1.10. Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.

- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

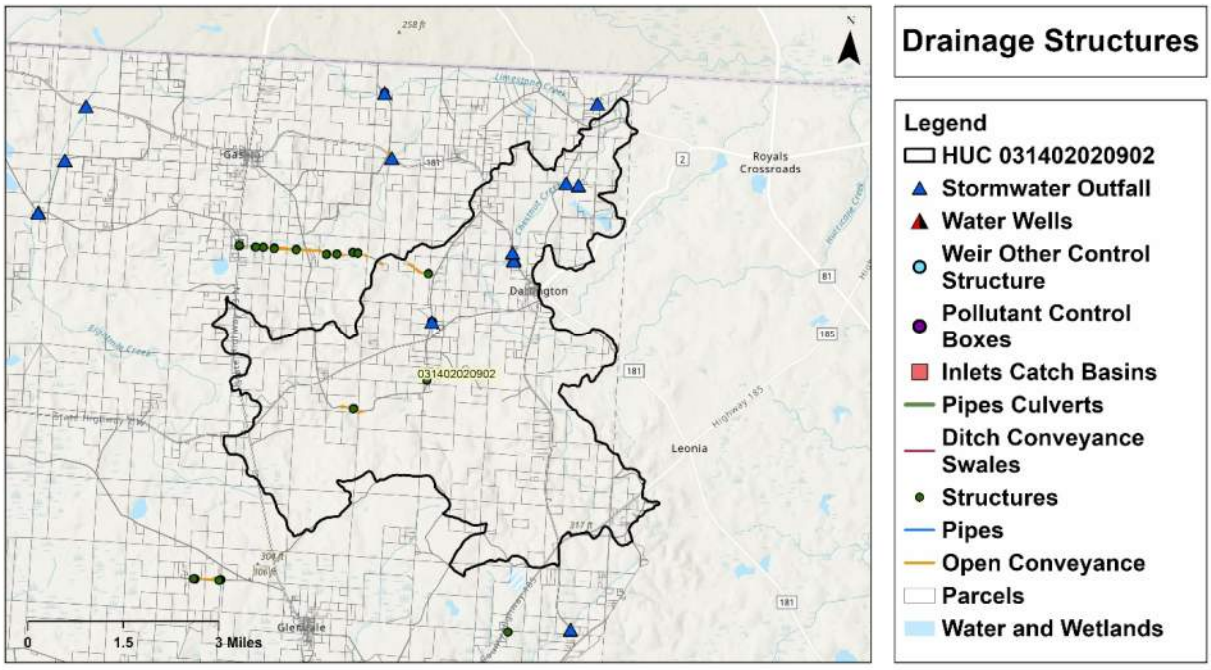

Figure 27. Stormwater Infrastructure for the HUC 031402020902. Processed by FAU.

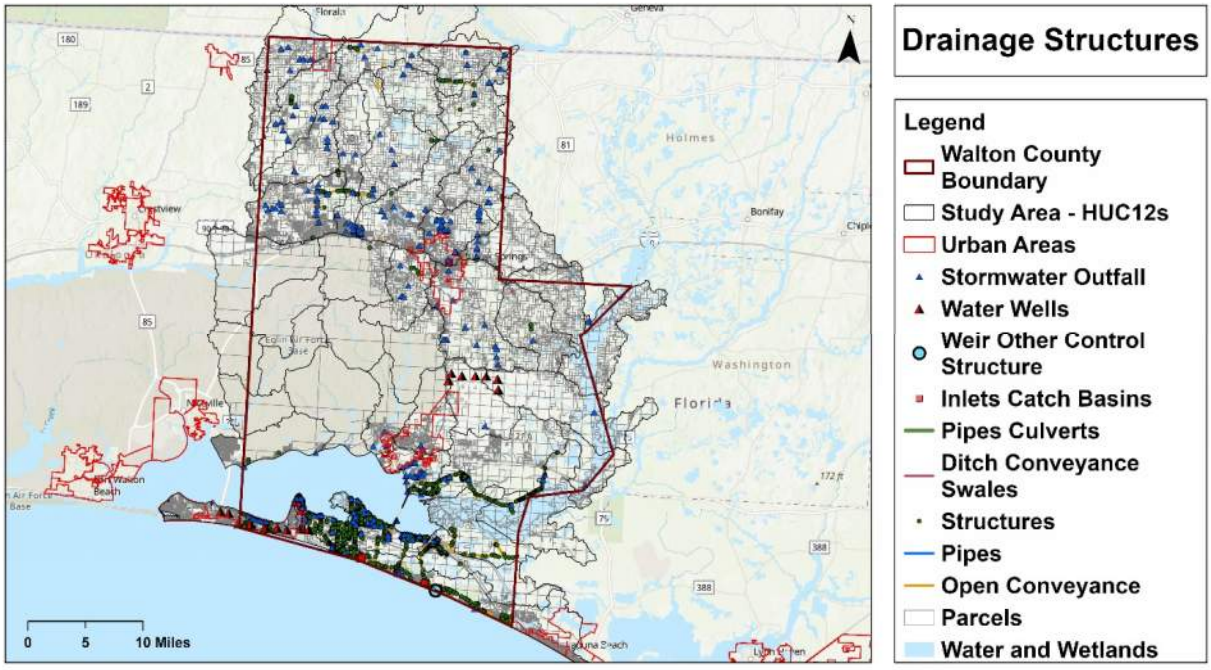

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapter 1, an analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031402020902 sub-watershed flood response to a series of rainfall events (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.3.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species

while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

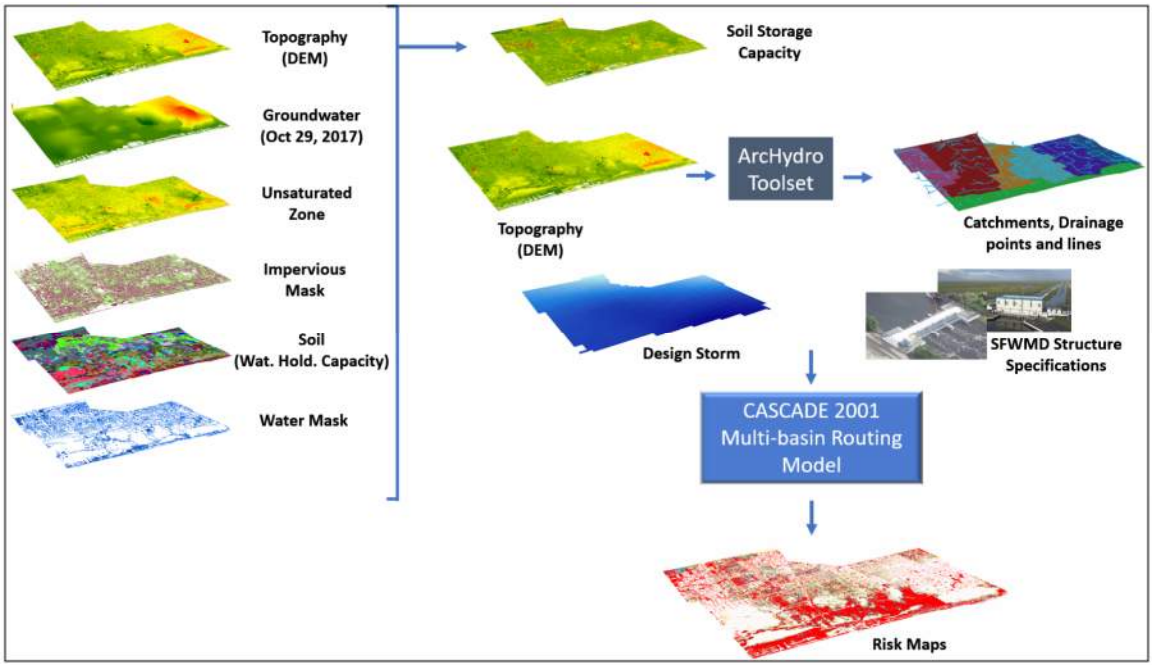

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

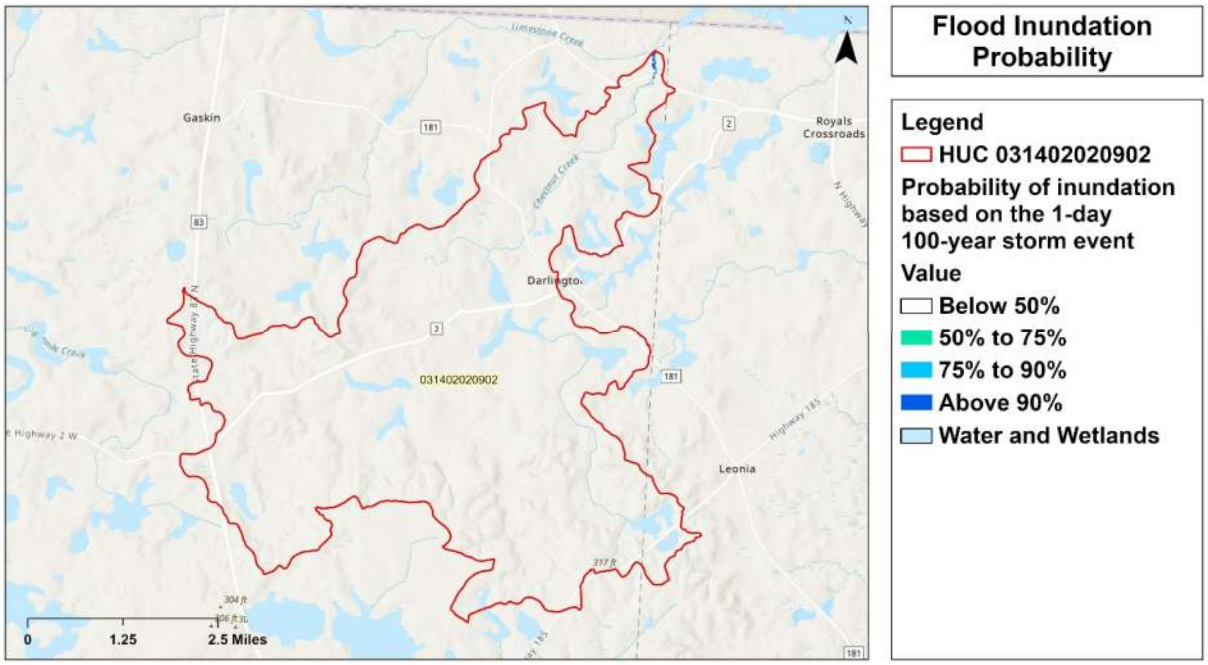

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031402020902, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate

the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 2.4 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a small portion of flooding, almost imperceptible, is noted at the creek entrance to the HUC. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 0.07% of the HUC total area or 0.02 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 0.05% of the HUC's total area, or 0.01 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 0.03% of the HUC's total area, or 0.01 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 0.03% of the HUC's total area, or 0.01 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031402020902 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	24.595	0.016	99.93%	0.07%
1-day 100-year	24.598	0.013	99.94%	0.05%
1-day 10-year	24.602	0.009	99.96%	0.03%
1-day 5-year	24.603	0.008	99.96%	0.03%

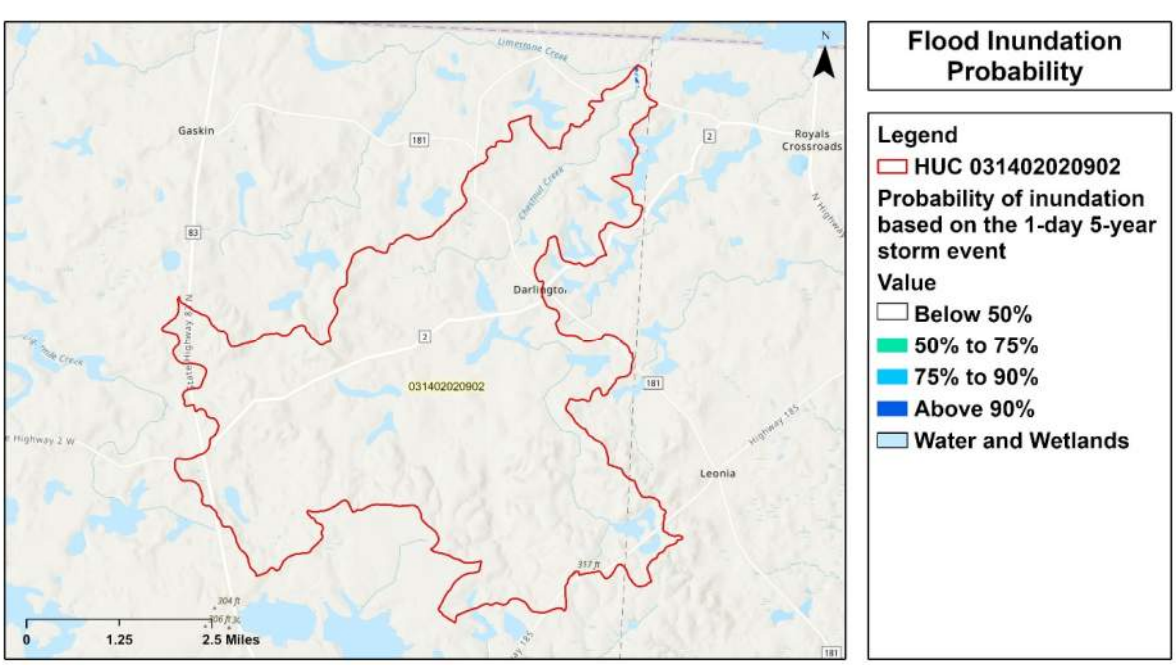

Figure 34. 1-day 5-year storm event for HUC 031402020902 sub-watershed.
Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations. Processed by FAU.

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

DOR (Use code)	**Description**	**TIER (Priority of Land Use)**
0	Vacant Residential	6

102	Parcels With no Values (Water)	6
103	Parcels With no Values (Rail)	2

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031402020902 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (Figure 35) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 36) overlays critical facilities onto the 1-day

100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

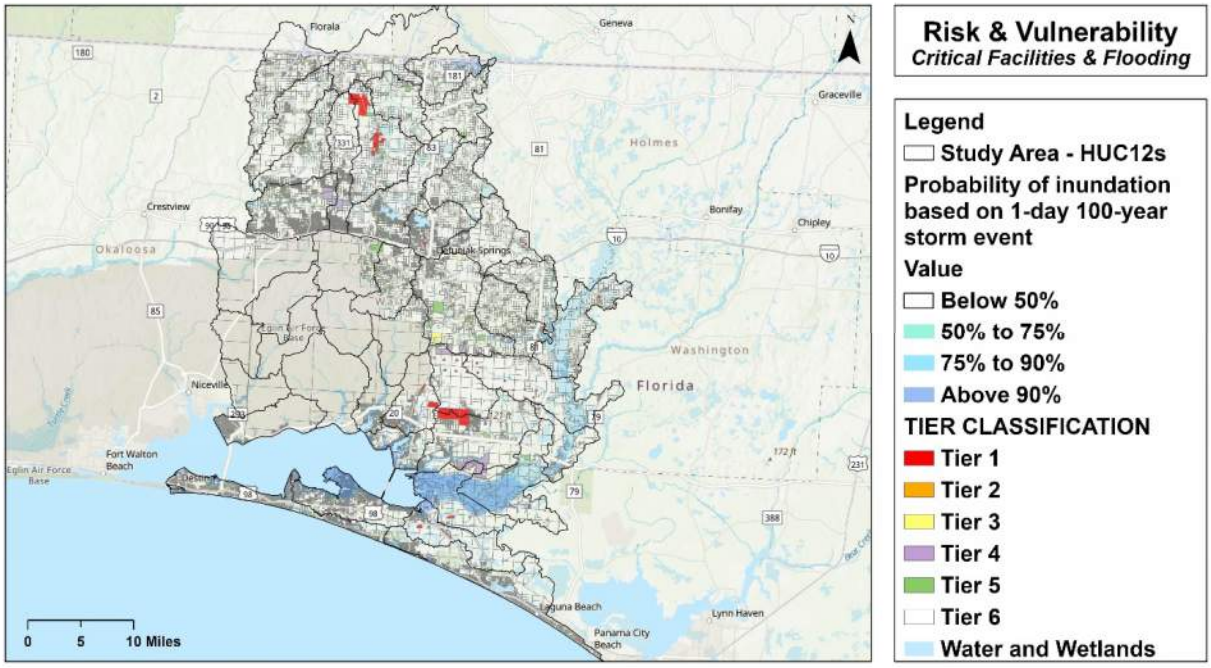

Figure 37. Walton County (mosaic) - Critical Facilities (priority of land uses) map overlaid on the 1-day 100-year storm event probability of inundation for Walton County. Processed by FAU.

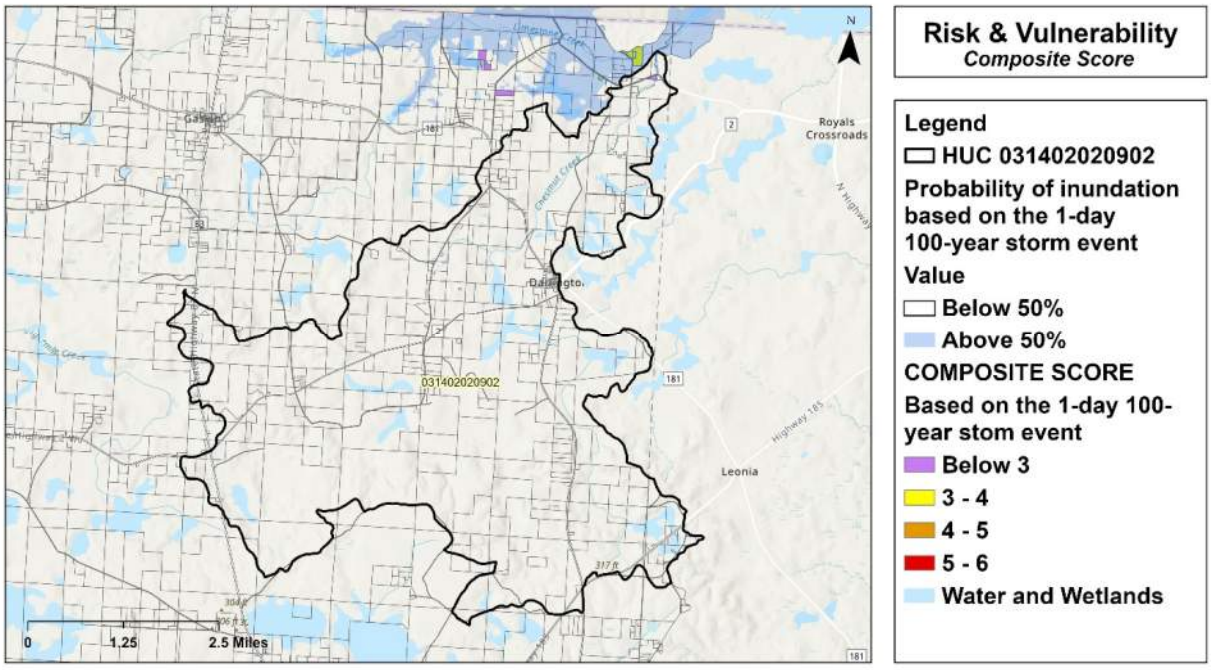

Figure 38. HUC 031402020902 sub-watershed Composite Score Risk map, with calculation based on 1-day 100-year storm event. Processed by FAU.

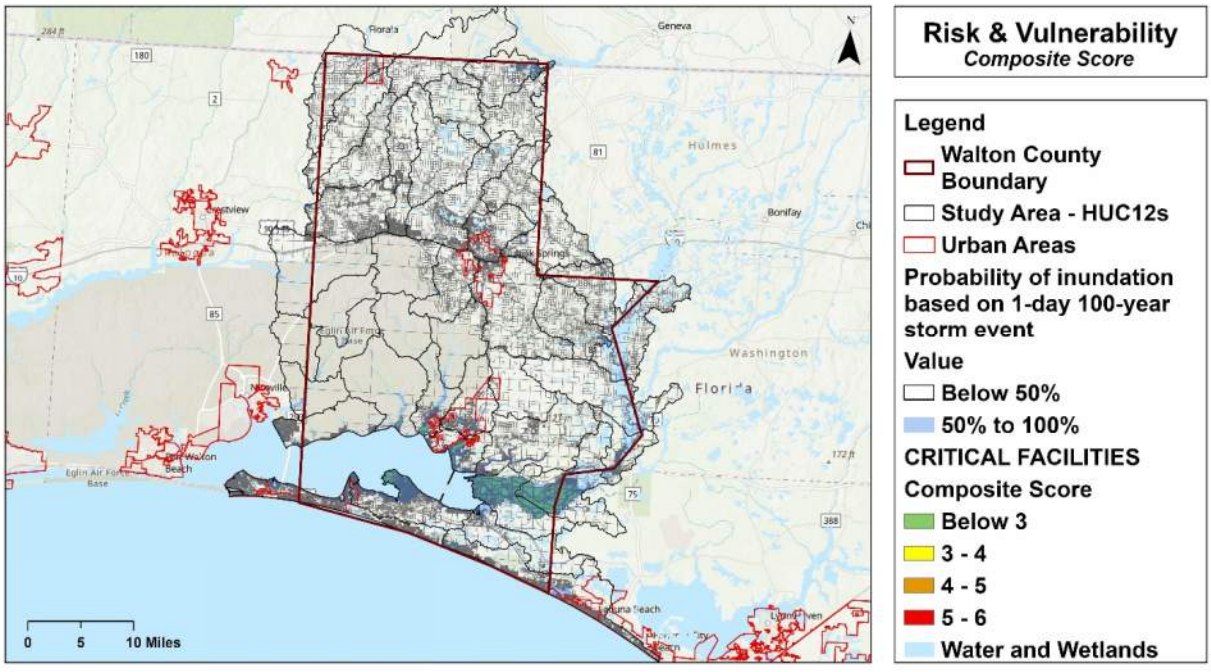

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.
Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031402020902. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located

within it. It's important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031402020902. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031402020902	15751.67
All of the 1-day 100-year storm event inundation	**8.38**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	0
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	8.38
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	8.38

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

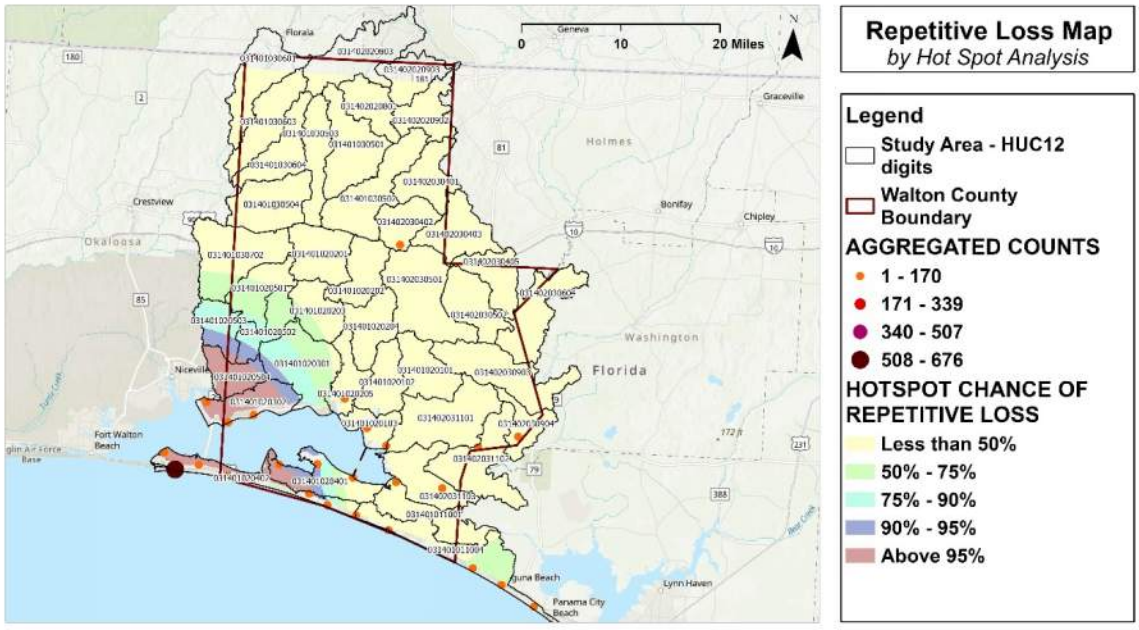

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although there are some parcels falling within tiers 2 (roads), 3, 4 and 5 of priority of land uses, none of them are within the flooding zone, once flooding in the area is minor and not alarming. Consequently, when considering the composite score, it is notable that most of the results are null,

indicating no priority for intervention within the basin. There are only three exceptions within the basin: a mobile home parcel with a score below 3, and two roads—Oak Grove Road, with a score of 4-5, and Cook Road, with a score of 5-6, indicating the highest priority for intervention.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**,, the HUC-12 (031402020903) is highlighted among all the HUCs to help identifying its location. (Figure 3).

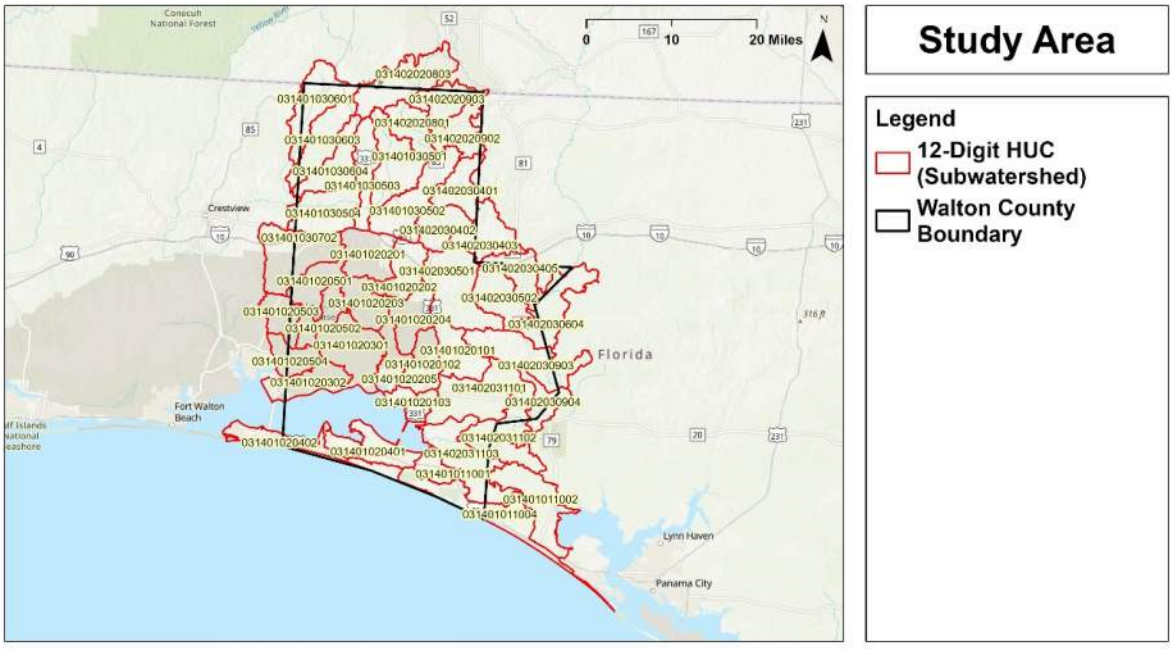

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

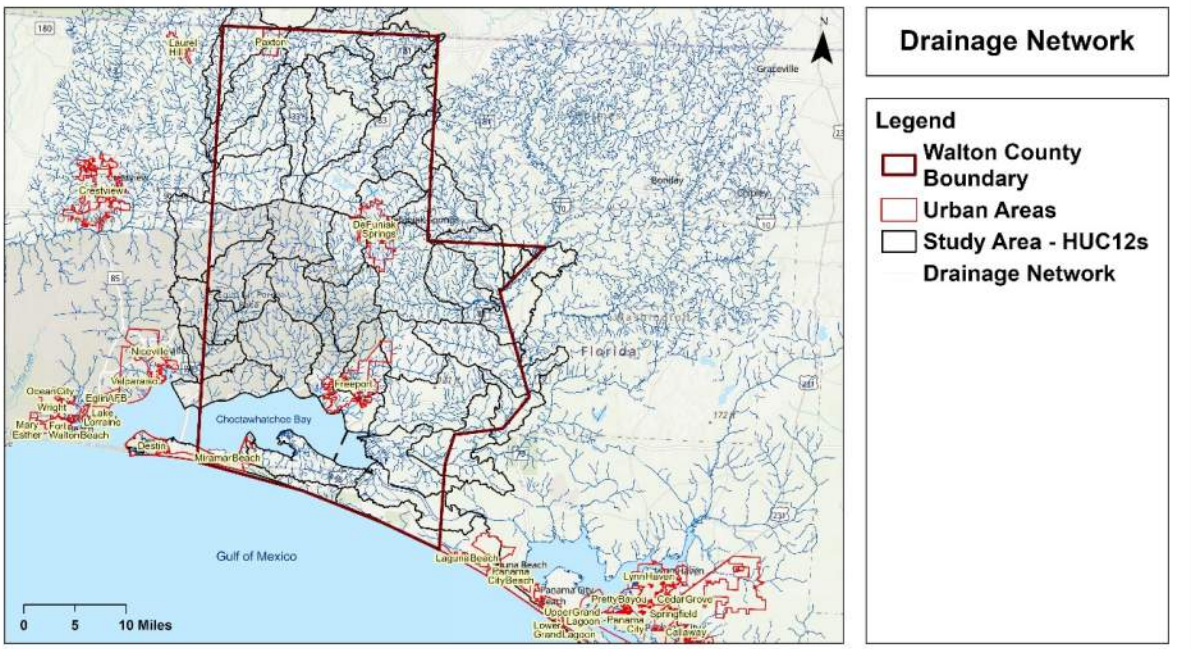

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

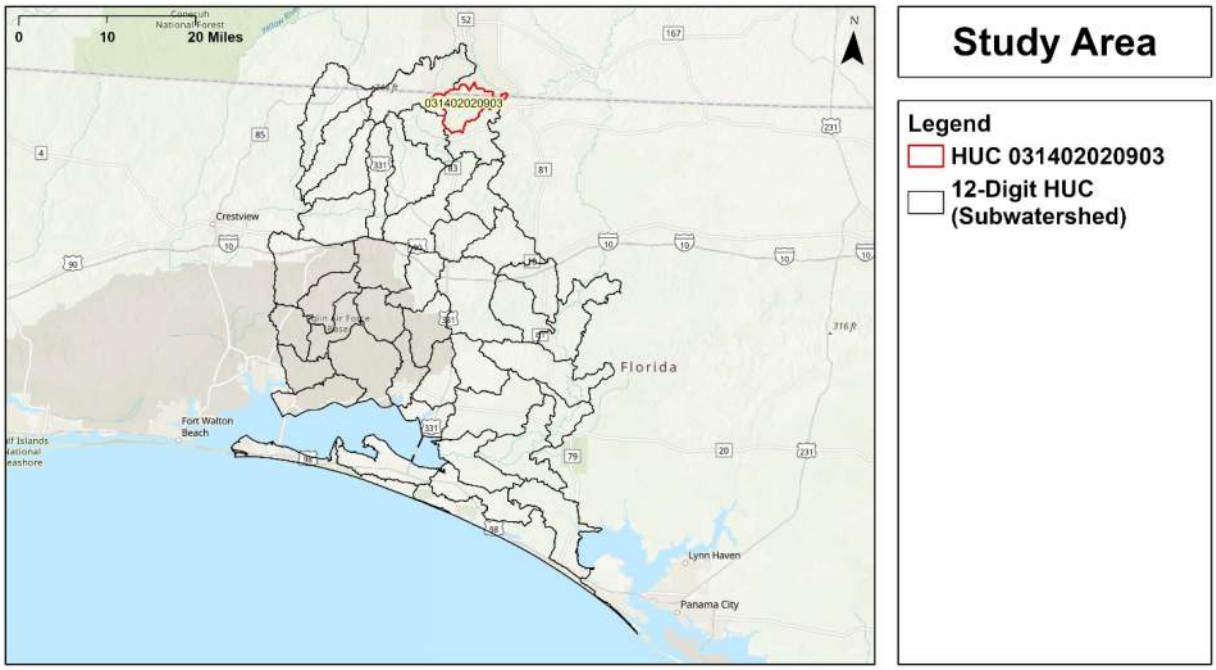

Figure 3. HUC 031402020903 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in Table 1. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

(Source Data: FEMA)

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

(Source Data: NWFWMD, 2017)

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.

April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

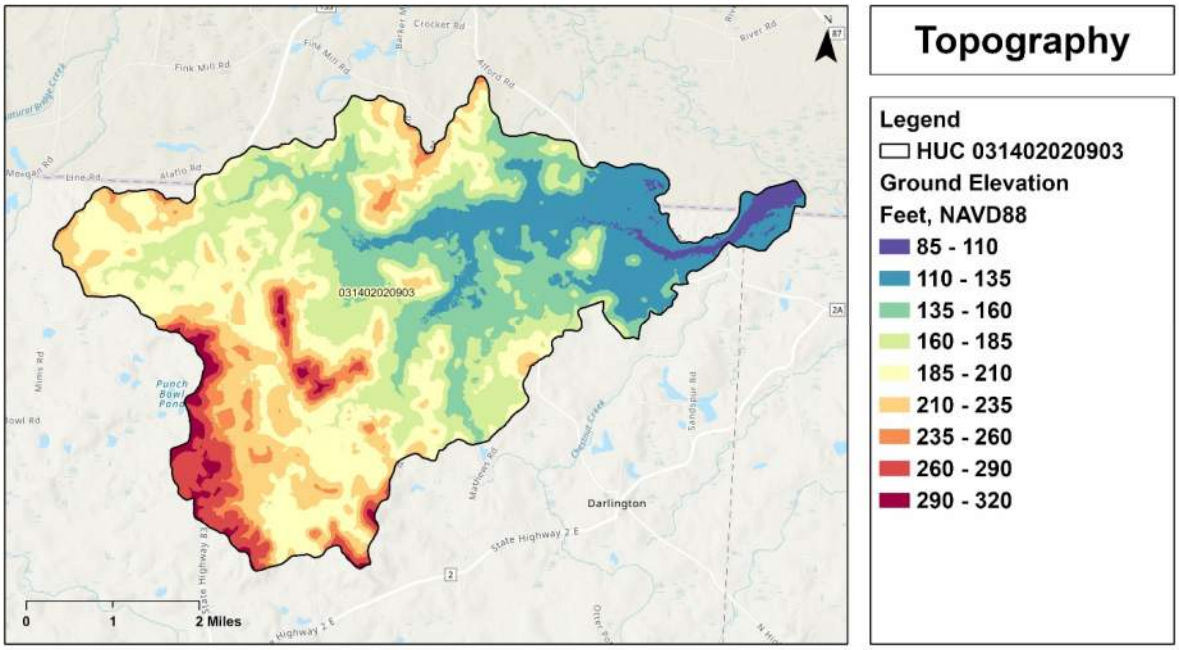

Figure 4. Topographic map of the HUC 031402020903 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031402020903 sub-watershed is shown in **Error! Reference source not found.**..

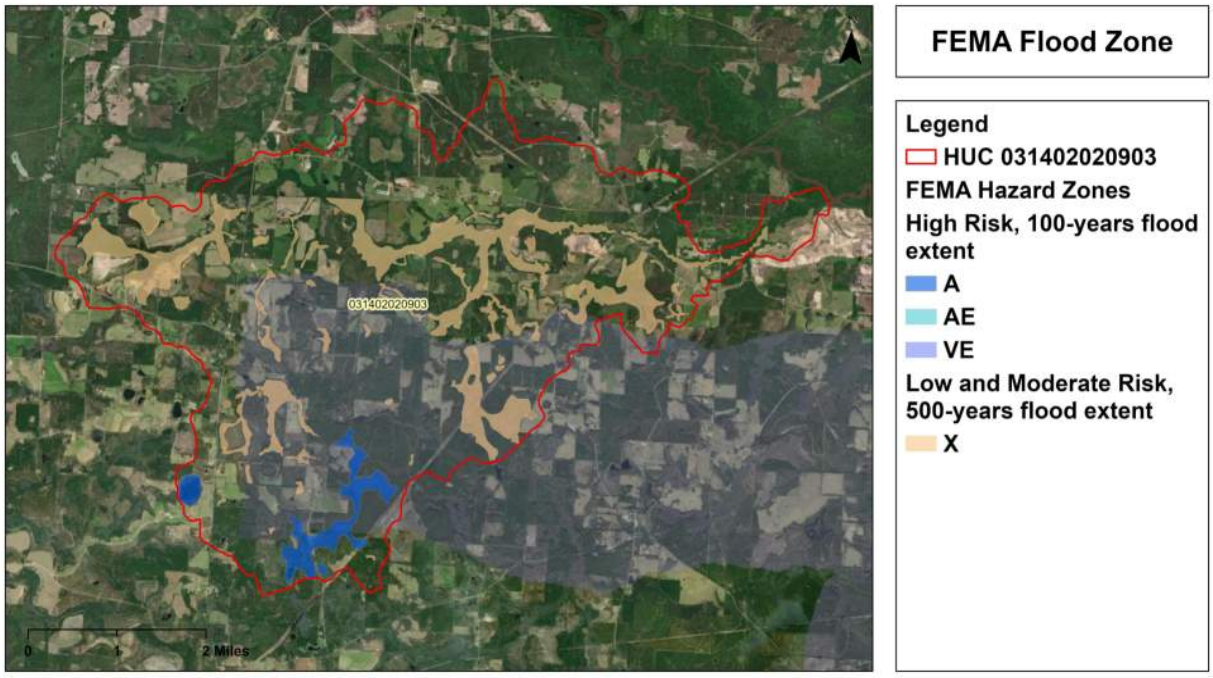

Figure 5. FEMA Flood Zone map (2020) for HUC 031402020903 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031402020903 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem.

This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

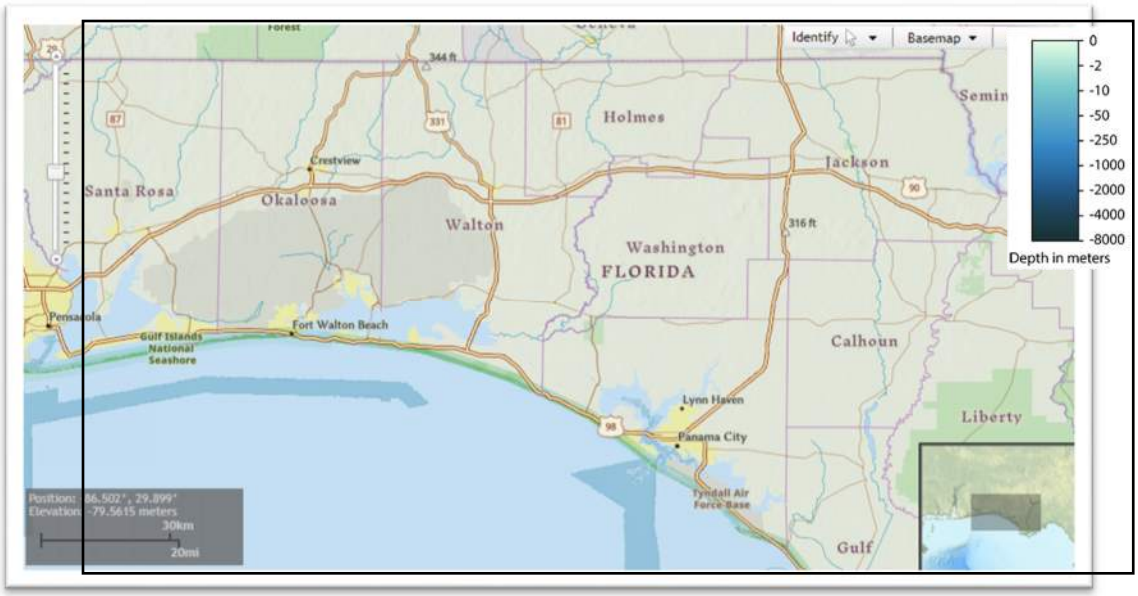

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

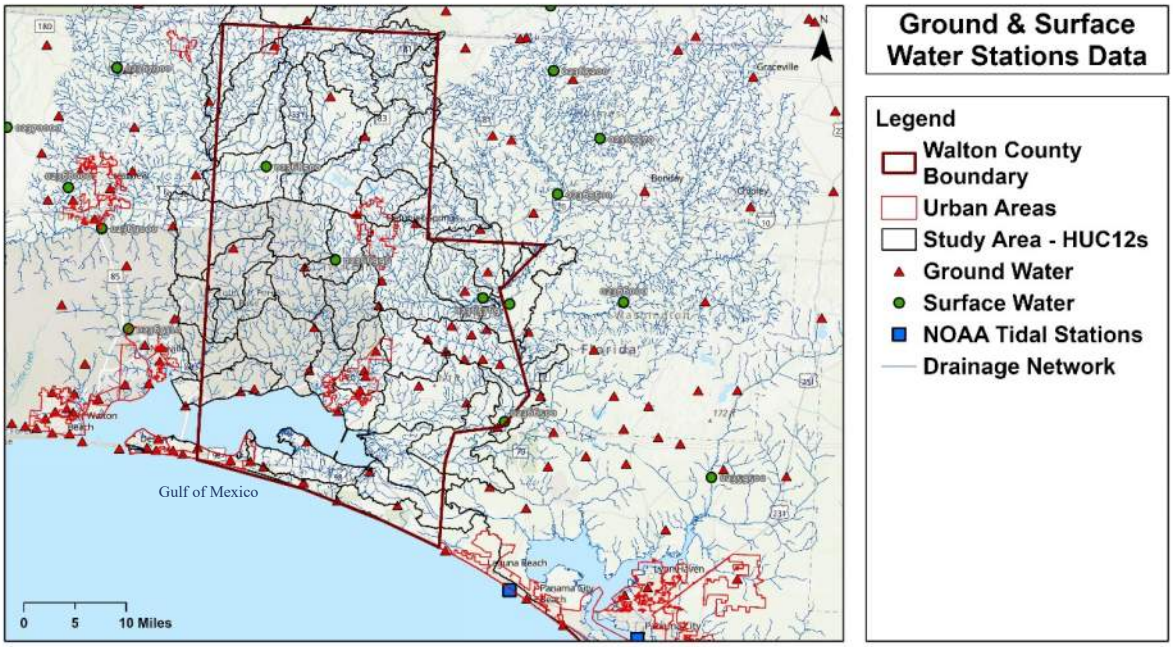

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031402020903 lacks major rivers and canals, instead featuring a network of well-branched creeks without specific names. These creeks originate in Alabama and flow in different directions though the basin.

Given that stream flow data are critical for estimating flooding, **Error! Reference source not found.** shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031402020903, which is USGS 02368500 Shoal River.

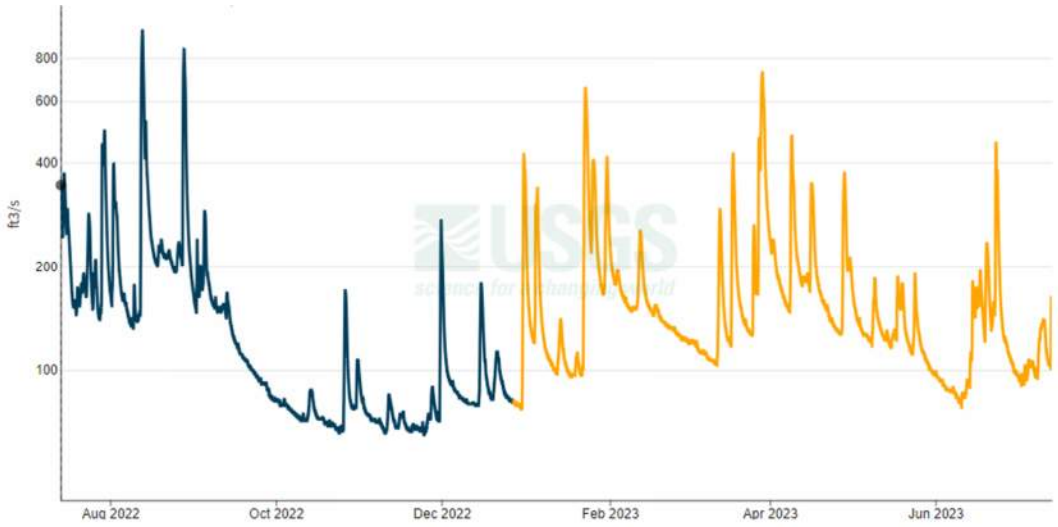

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station

(or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031402020903 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031402020903 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

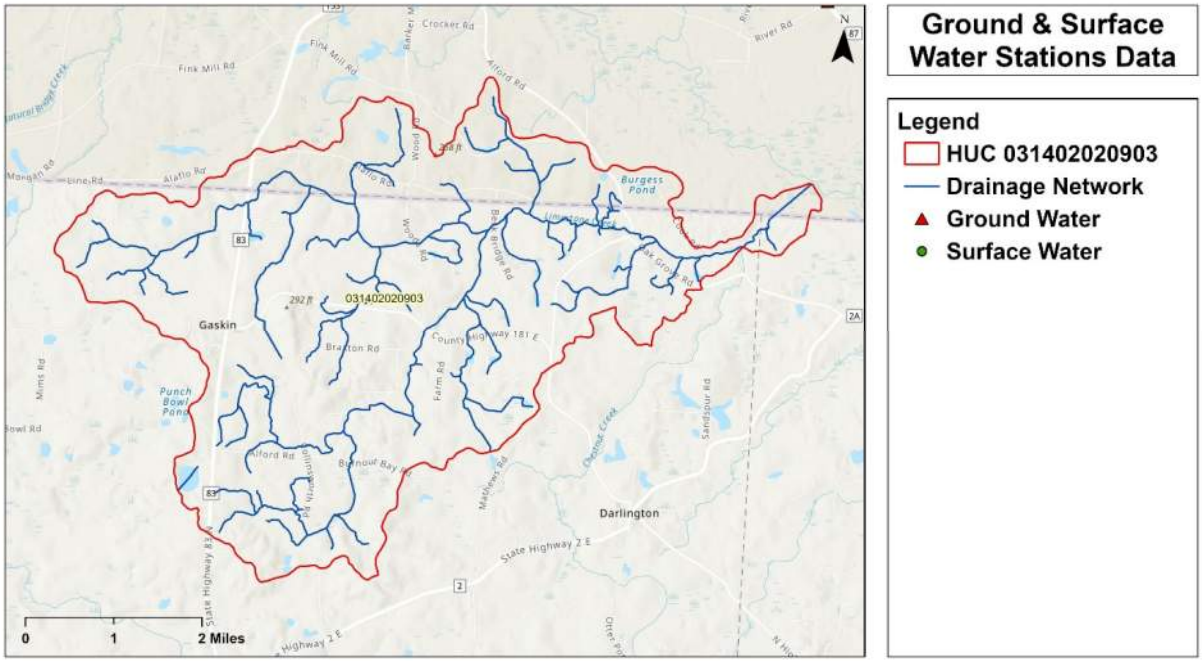

Figure 9. Ground and Surface Water Stations in the HUC 031402020903 sub-watershed, processed by FAU.

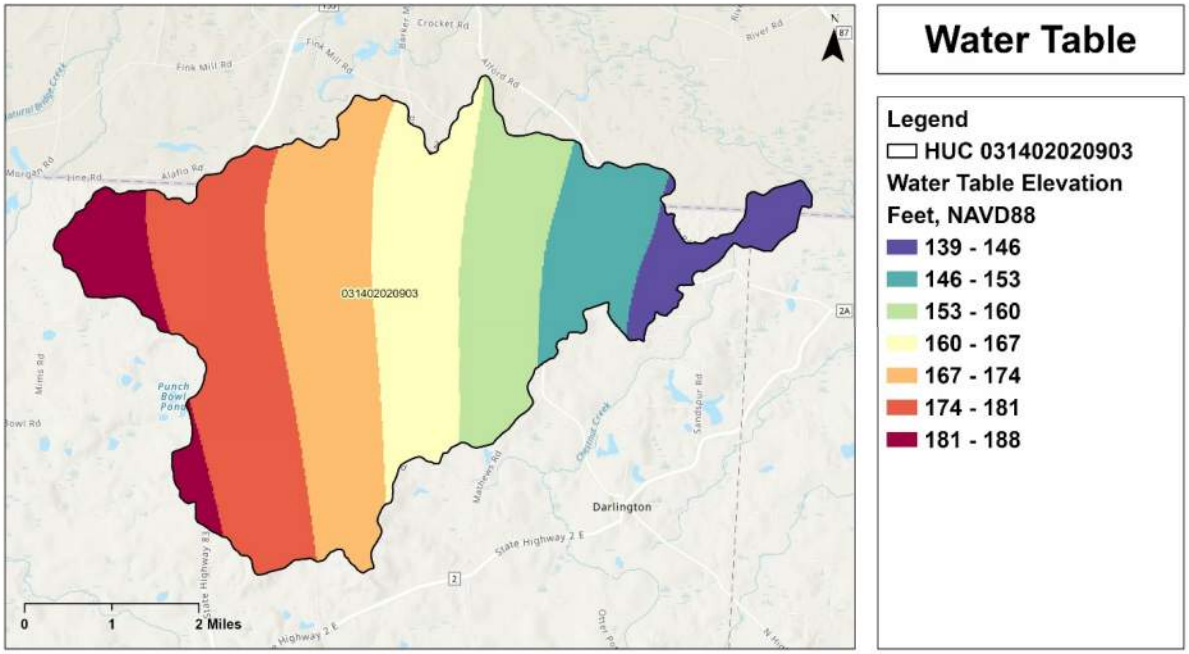

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031402020903 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

1.3 Surface Water/Tides

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the average precipitation over Walton County for every month of the year between 2011 and 2023 - each rectangle is a month and each column is a year. The 12-month total precipitation decreased 7.5 inches from May 1900 to April 2023. From May 1900 to April 2023, the average 12-month total precipitation was 60.5 inches for the entire county.

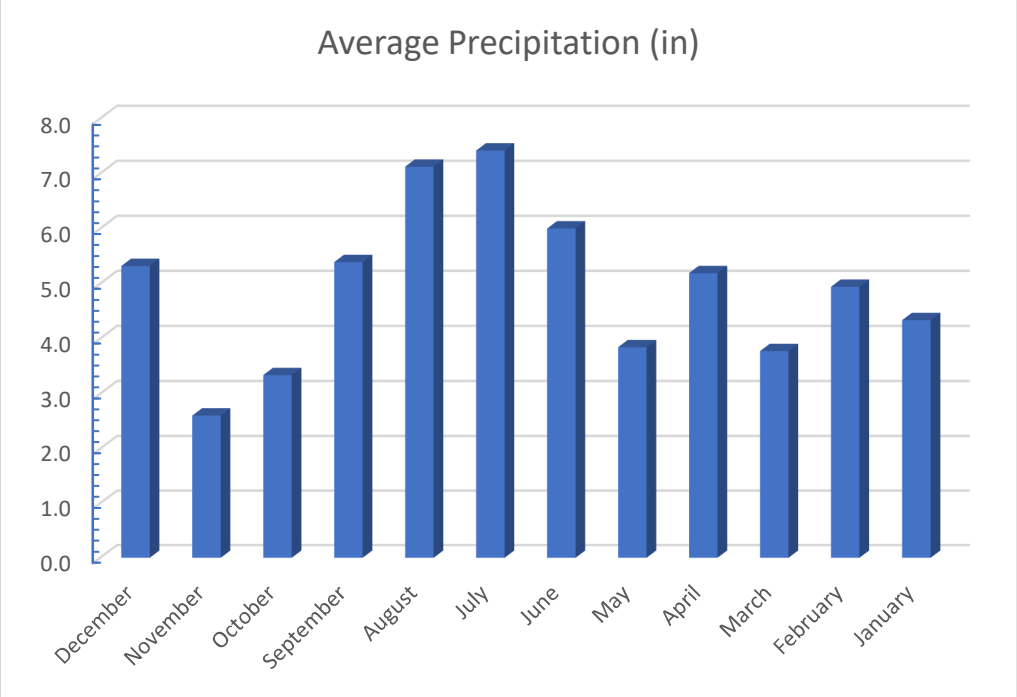

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4)create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as

opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. Figure 12 shows the two closest tide stations to Walton County. Since there is none NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

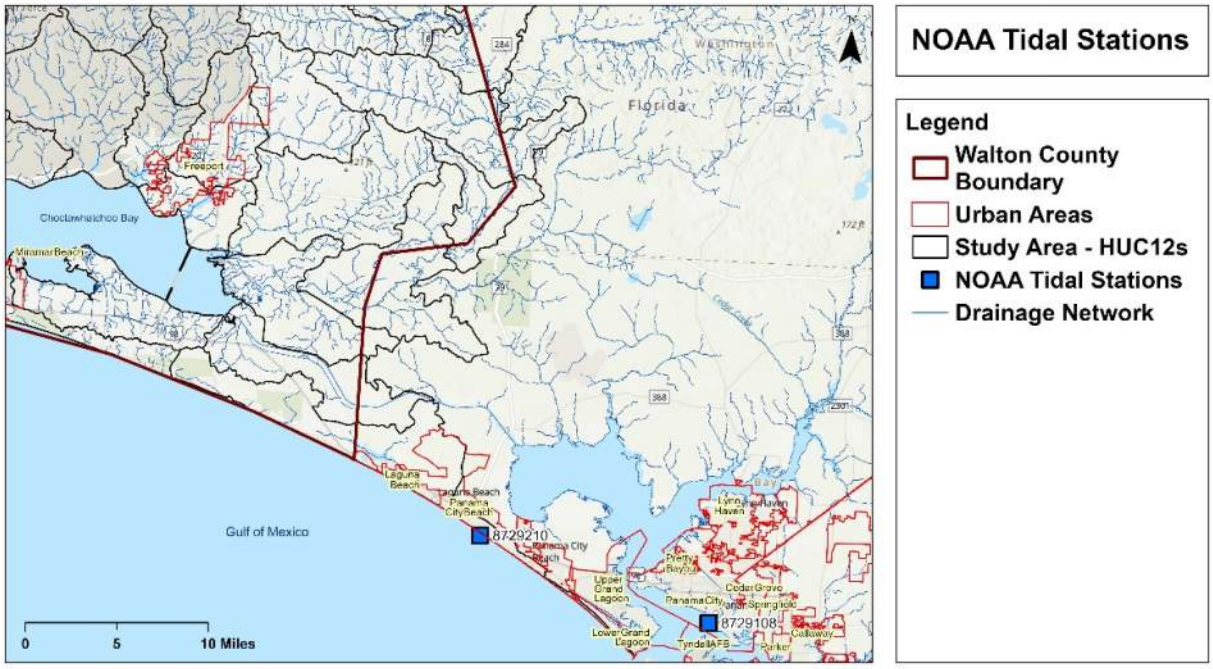

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

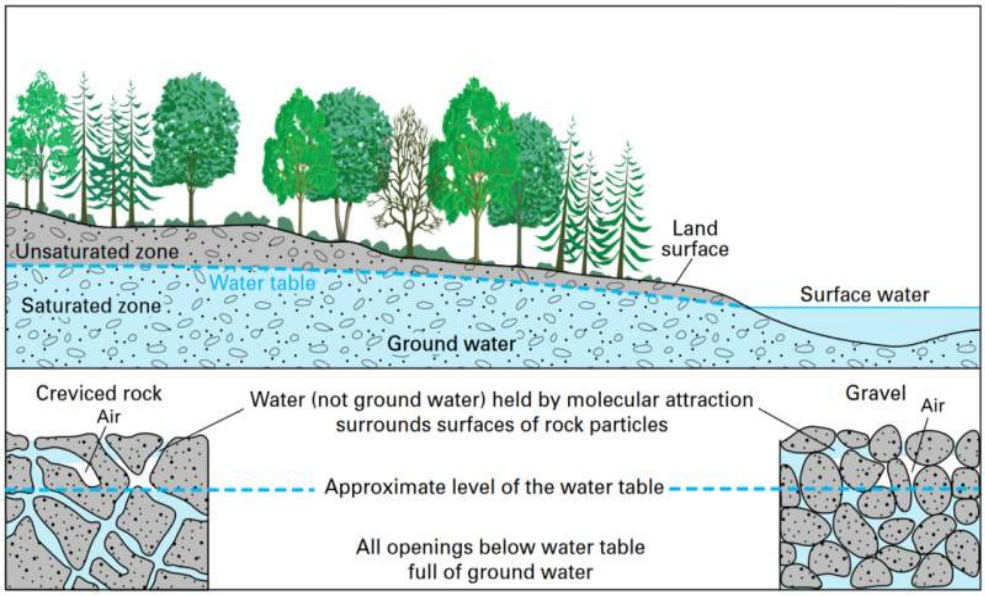

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in Figure 14. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

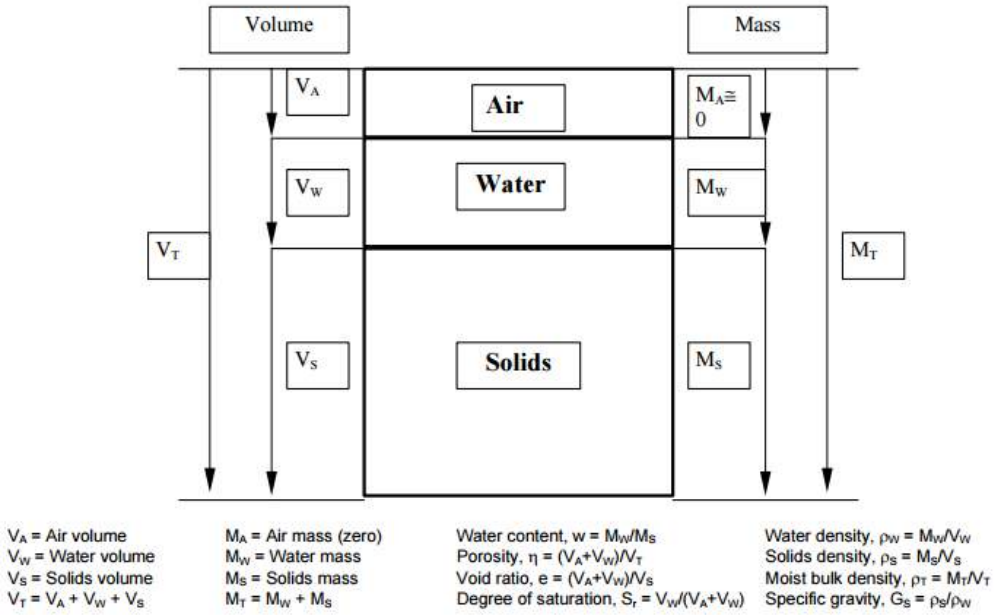

Figure 14. Saturated zone soil phase diagram and definitions .
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

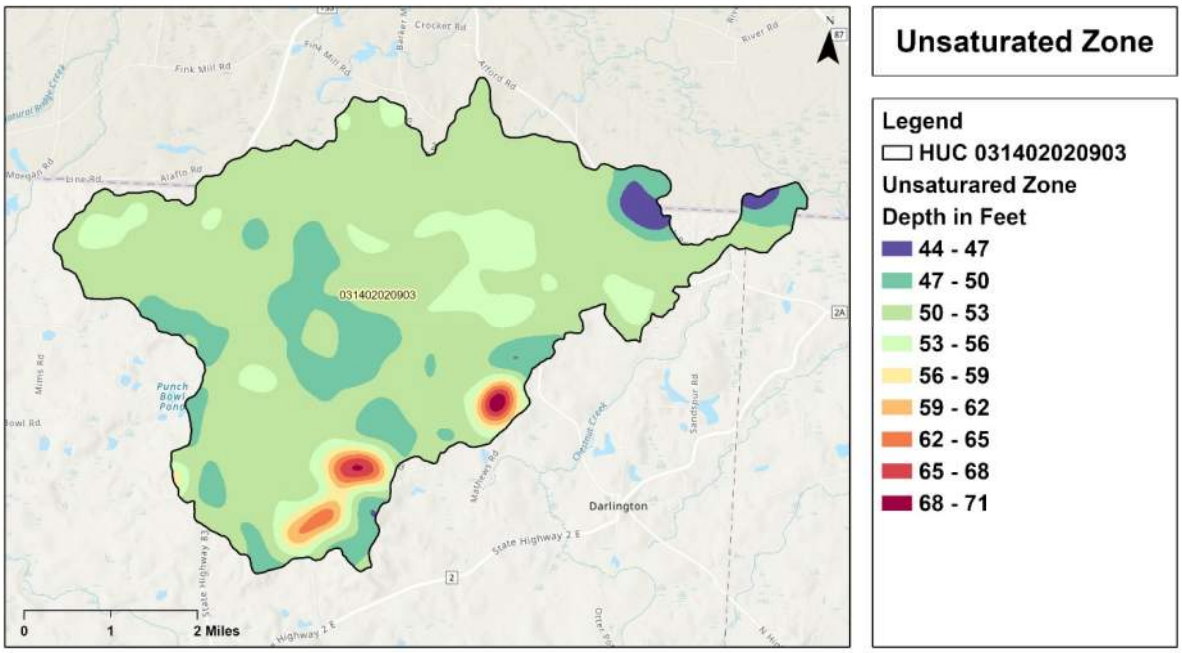

Figure 15. Unsaturated zone map for HUC 031402020903, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. The entire basin exhibits a favorable soil storage capacity, ranging between 44 to 71 inches of remaining capacity.

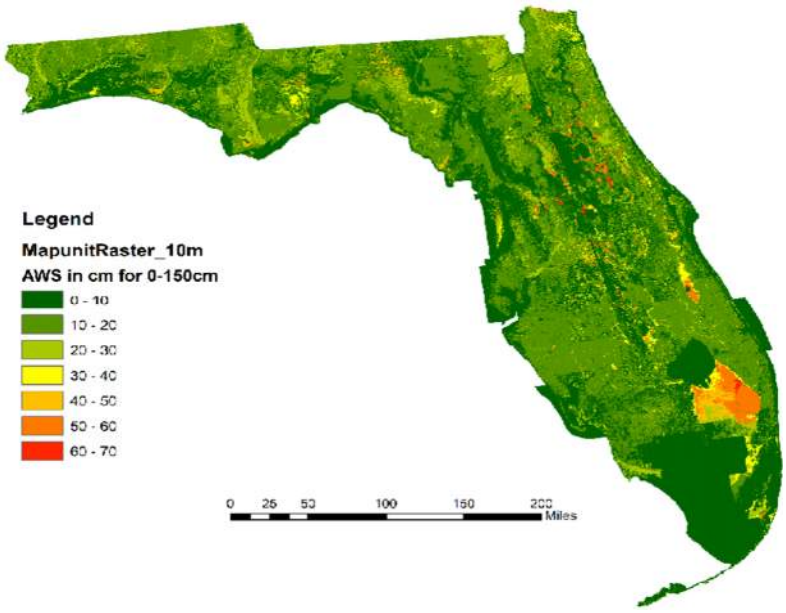

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

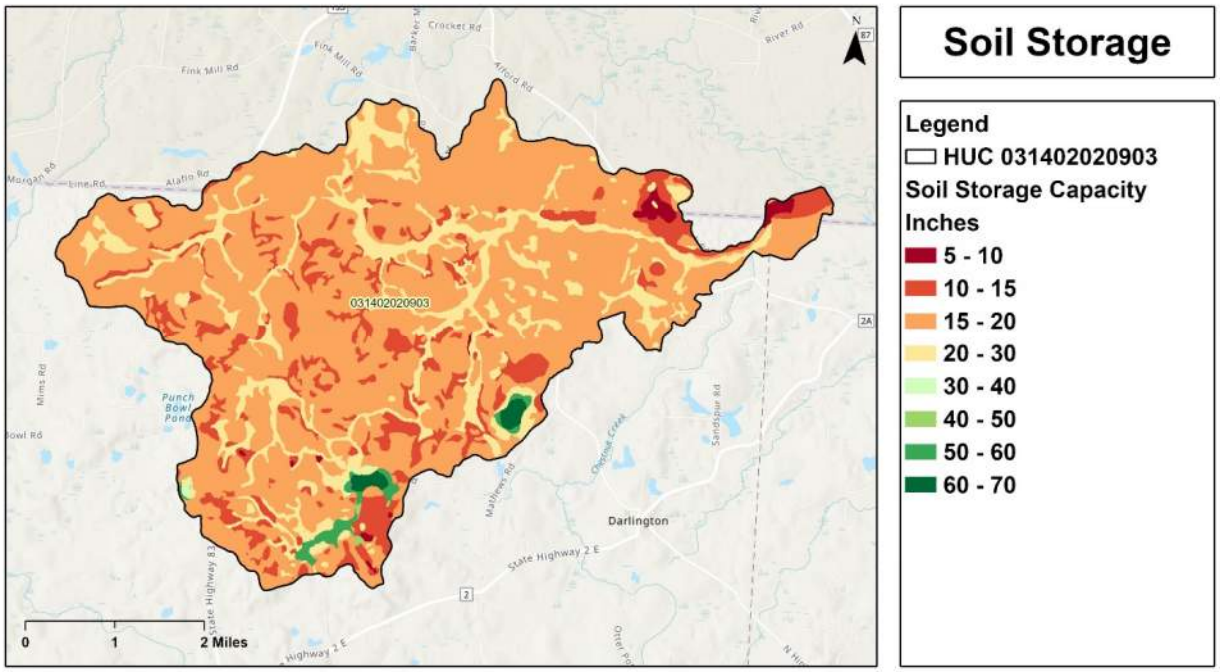

Figure 17. Water storage capacity of soil for the HUC 031402020903, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

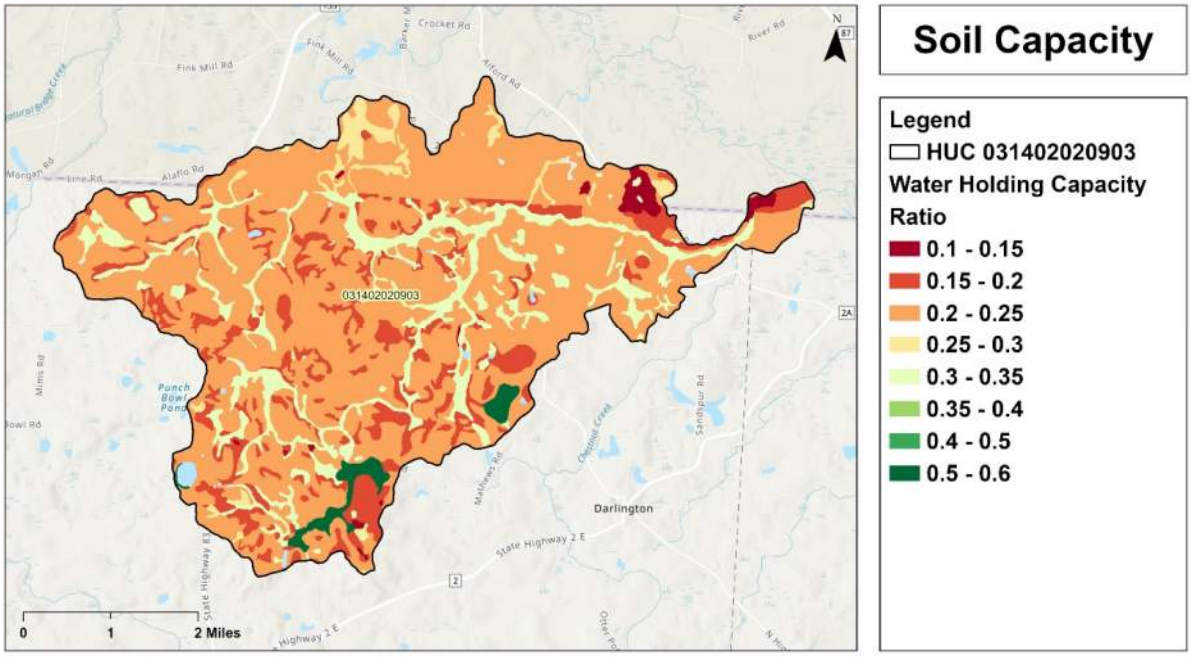

Figure 18. Water Holding Capacity (ratio) for the HUC 031402020903, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

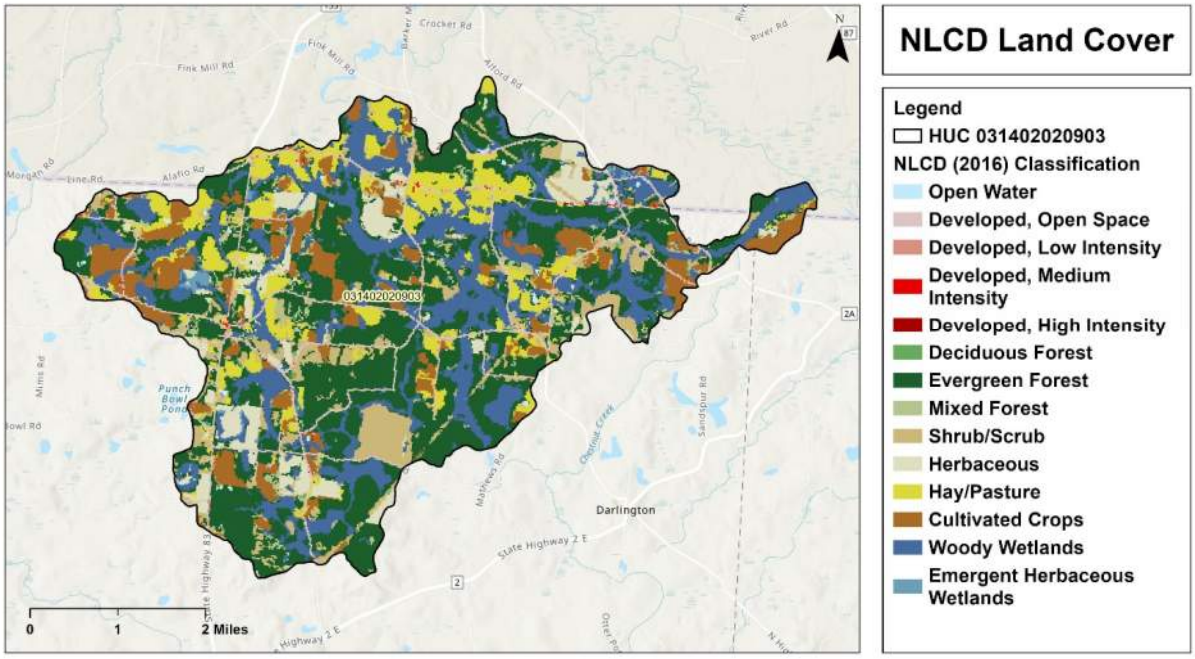

Figure 19. Land use in the HUC 031402020903 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD 2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

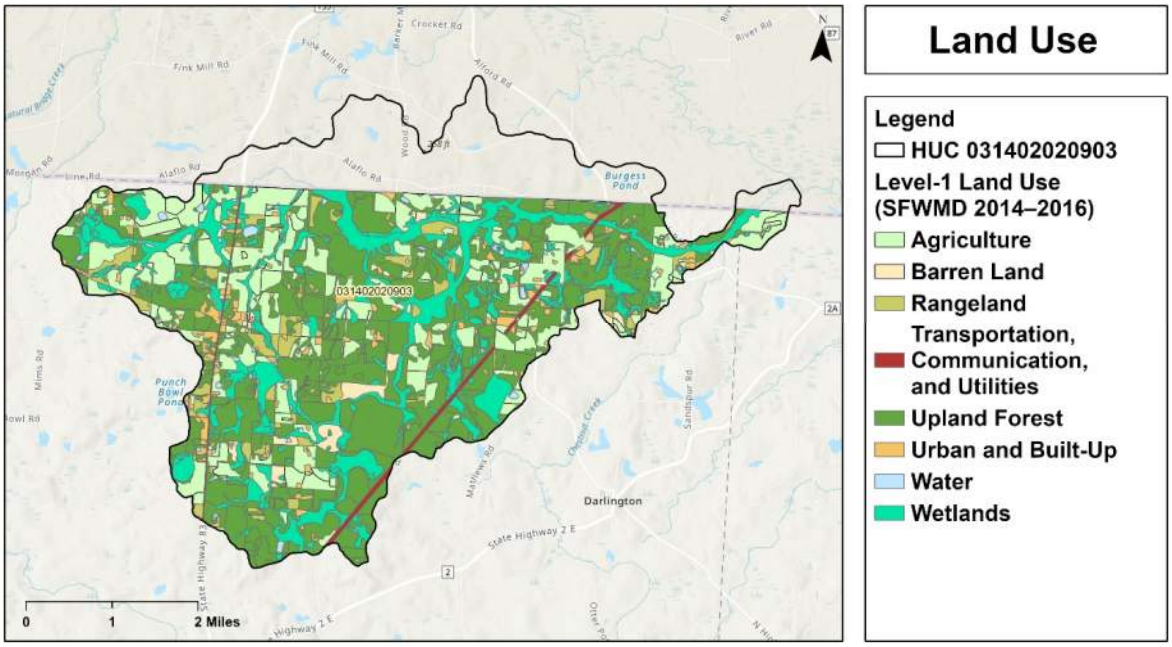

Figure 20. Land use in the HUC 031402020903 ((from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

Please be aware that the Alabama portion of the HUC was not considered in this land use study. Consequently, the following analysis pertains solely to the Florida portion of the HUC 031402020903 sub-watershed. In this area, the predominant land cover is upland forest, accounting for 37.70% of the region. Agriculture comes in second at 21.39%, followed by Transportation, Communication, and Utilities at 16.83%. Developed land is limited, with only 2.71% categorized as urban and built-up, as illustrated in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031402020903 subwatershed

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	3711.97	21.39%
Barren Land	216.82	1.25%
Rangeland	720.79	4.15%
Transportation, Communication, and Utilities	2921.21	16.83%
Upland Forest	6544.03	37.70%
Urban and Built-Up	470.47	2.71%
Water	109.57	0.63%
Wetlands	2662.94	15.34%
Grand Total:	**17357.80**	**100.00%**

(Source Data: 2023 Florida Geographic Data Library (FGDL) database))

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

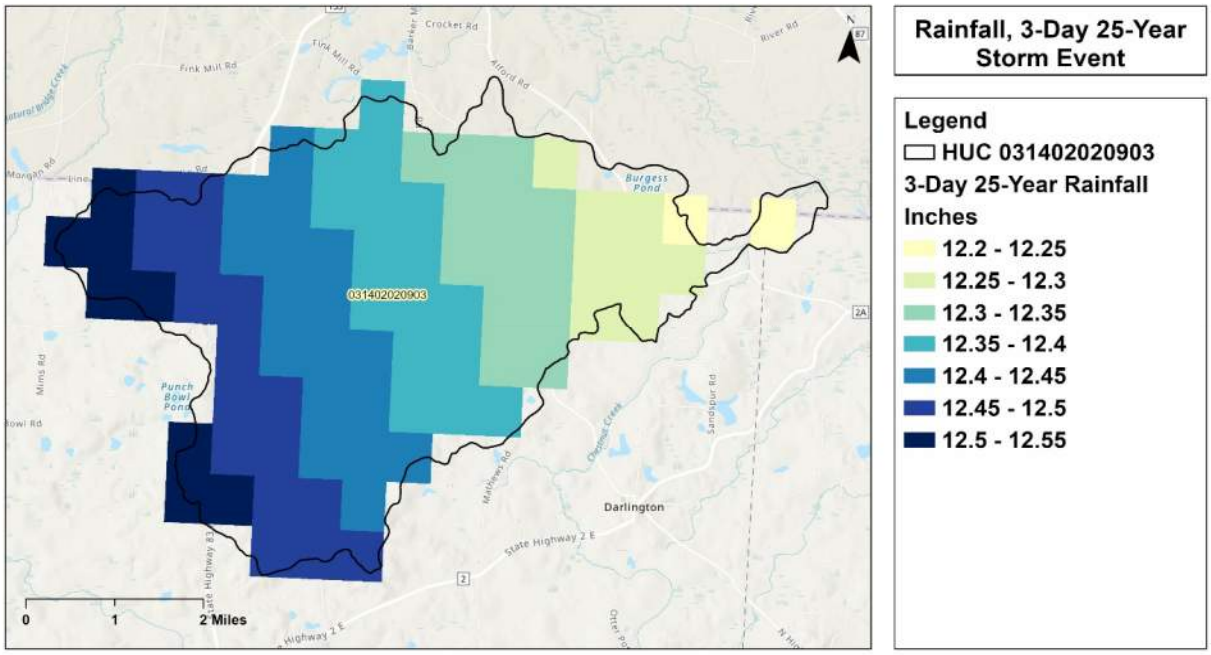

Figure 21. Rainfall distribution map across HUC 031402020903 sub-watershed, for 3-day 25-year storm event, processed by FAU.

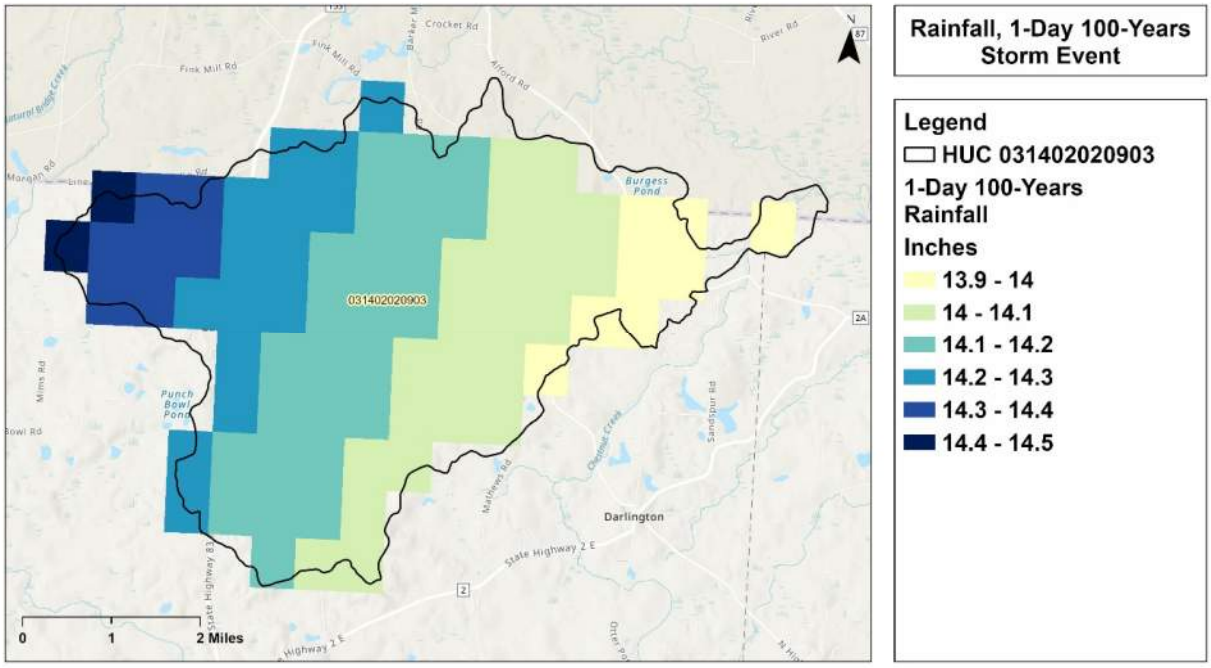

Figure 22. Rainfall distribution map across HUC 031402020903 sub-watershed, for 1-day 100-year storm event, processed by FAU.

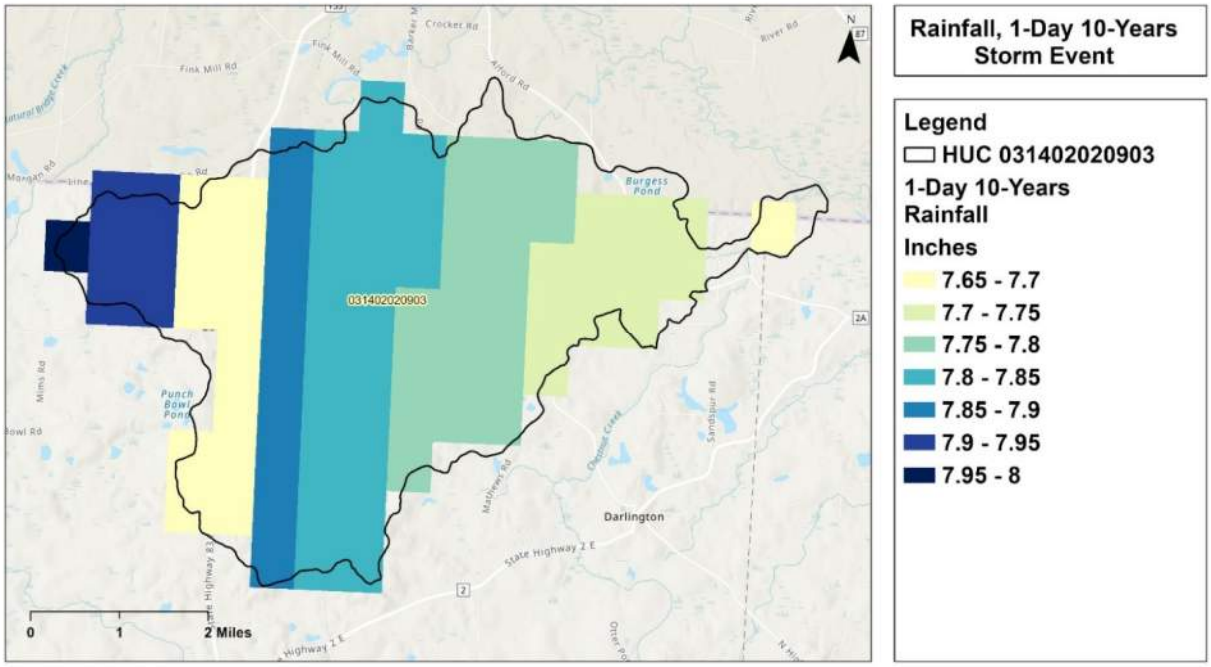

Figure 23. Rainfall distribution map across HUC 031402020903 sub-watershed, for 1-day 10-year storm event, processed by FAU.

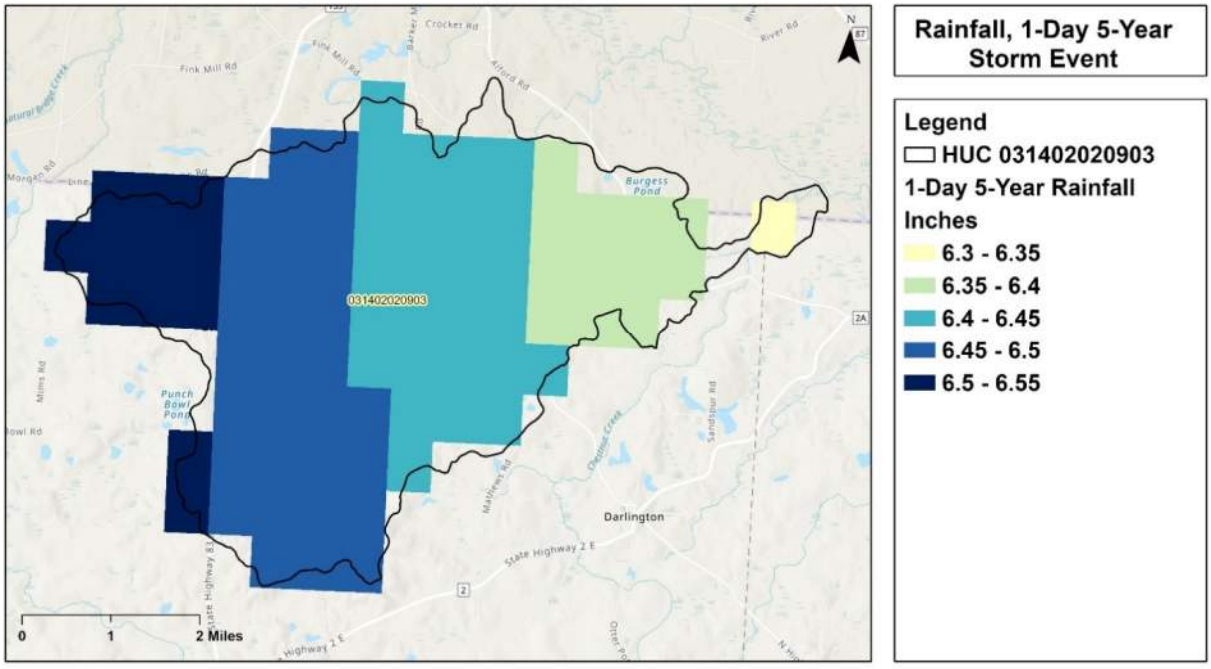

Figure 24. Rainfall distribution map across HUC 031402020903 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.

The NLCD provides nationwide data on land cover and land cover change at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. Systematically aligned over time, the database offers the ability to understand both current and historical land cover and land cover change to enable assessment of trends. Using the NLCD 2016 dataset, a layer was created by using only three categories out of the 13 to identify impervious areas such as primary roads in urban areas, secondary roads in urban areas, and tertiary roads in urban areas. The new layer was then converted to match the 3-meter spatial resolution from the DEM and the standard State Plane Coordinate system. **Error! Reference source not found.** shows the impervious areas derived from the NLCD 2016 as updated by the future land use map.

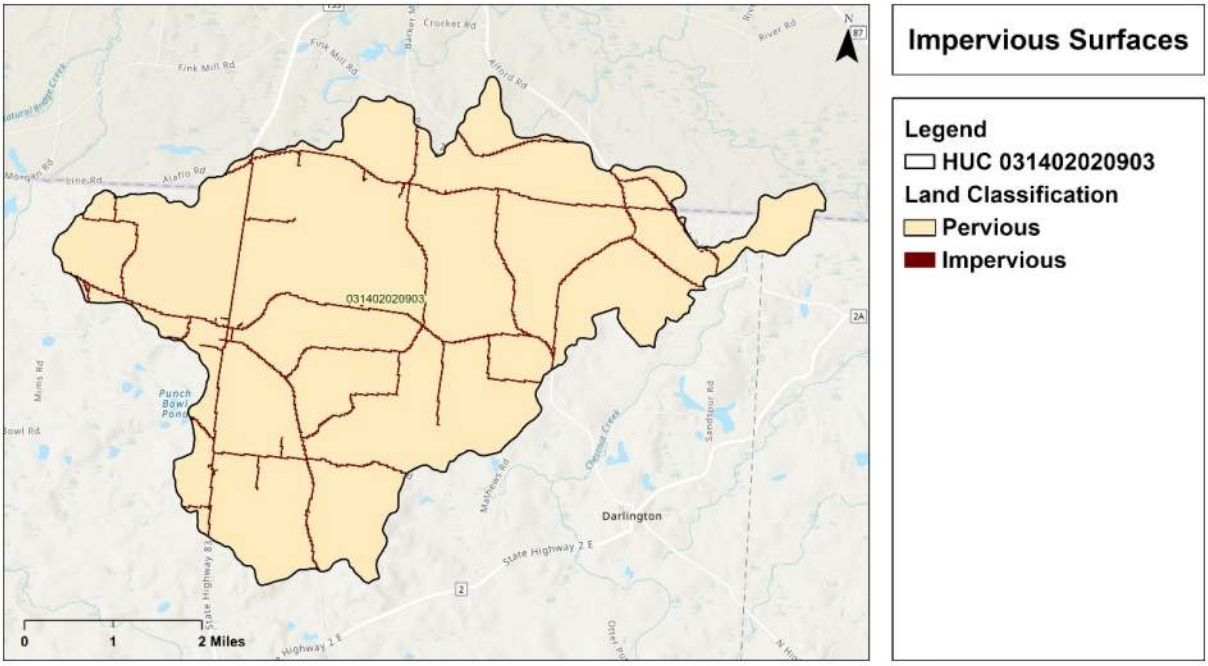

Figure 25. Impervious area map for the HUC 031402020903 sub-watershed, processed by FAU.

1.9 Water bodies

Water bodies were defined in the statewide land use land cover dataset to set soil water holding capacity to zero in model simulations (**Error! Reference source not found.**). Note that tiny water bodies may be missing from the maps. Soils were discussed previously in Section 1.4.

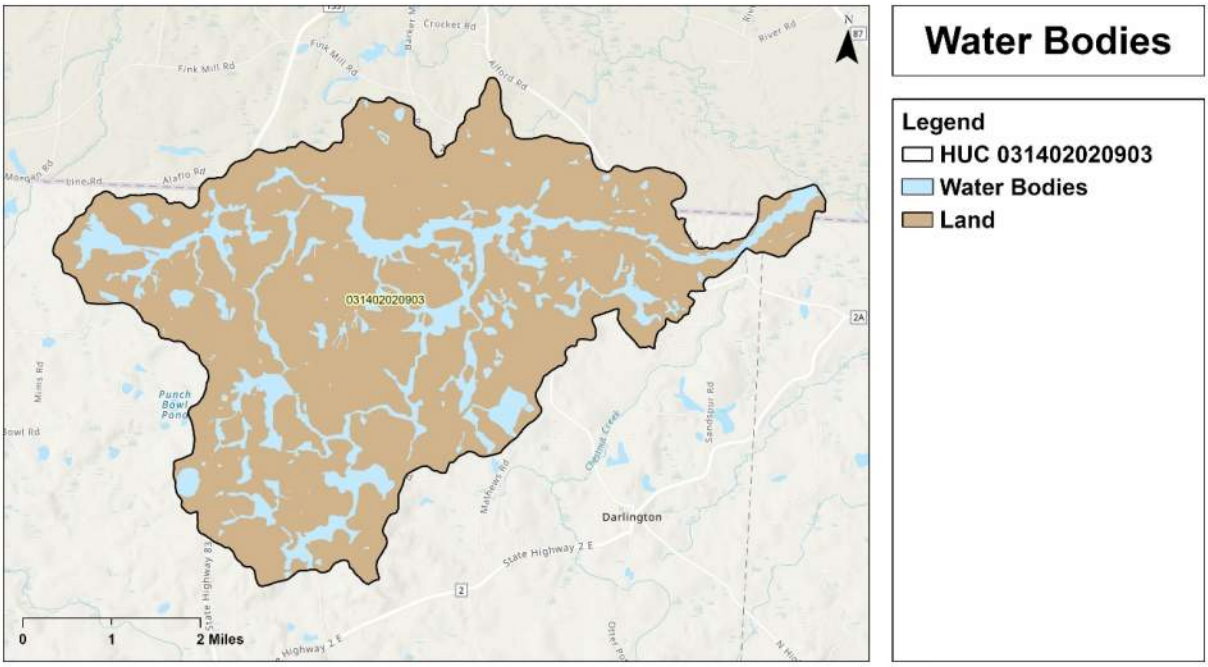

Figure 26. Water bodies map for the HUC 031402020903 sub-watershed, processed by FAU.

1.10 Natural Resources

Understanding the study area's natural resources is critical to identifying potential sources of water quality degradation and areas to designate for conservation, protection, and restoration. One possible goal of watershed master planning is to protect terrestrial wildlife, aquatic habitat, and buffer zones. USGS maintains important sources of information on physical and geographical features as well as soil and mineral resources, surface and ground water resources, topographic maps, and water quality monitoring data. The USDA's Natural Resources Inventory (NRI) (www.nrcs.usda.gov/technical/NRI) is a survey of information on natural resources on non-federal land in the United States that captures data on land cover and land use, soil erosion, prime farmland soils, wetlands, habitat diversity, erosion, conservation practices, and related items. Since 2001, the NRI has been updated continually with annual releases of NRI data from all 50 states. The information provided can be used for addressing agricultural and environmental issues down to the county or cataloging unit level. Therefore, this data can be used to determine erosion and site-specific soil characteristics for certain land uses such as croplands, pasturelands, forestlands, etc., but the data is typically provided as inventories, not GIS layers.

1.11 Demographics

Demographics data is important for determining several key indicators for watershed master planning such as the ability to pay for improvements, social justice issues, land acquisition costs, property/land use, and communication strategies. The US Census has databases at the census tract level. Based on the census data for the study area, **Error! Reference source not found.** outlines population and racial composition demographics.

Table 5. Demographics and Housing Characteristics of Cities and Towns in Walton County.

Demographic Parameter	**Miramar Beach**	**Freeport**	**DeFuniak Springs, City**	**Paxton**	**Rosemary Beach**	**Santa Rosa Beach***	**Walton County**
Type	CDP**	City	City - County Seat	Town	Unincorporated community		County
Area in square miles	7.02	18.94	13.95	4.01	17,021	68,722	1,038.29
Population (Census 2020)	8,002	5,861	5,919	556	2,878	20,567	75,305
Total Households	4,334	2,206	2,509	316	1,318	8,275	30,182
Median Household Income	$75,347	$75,637	$53,984	$41.750	$127,148	$94,648	$68,111
Median Age	56.3 years	41.4 years	37.1 years	50.6 years	52.4 years	43.20 years	45.0 years

(Source: US Census Bureau 2020, and Zip-codes.com)

*It includes the communities of Point Washington to the East and a 15-mile stretch of the Emerald Coast from the east side of Miramar Beach to the west side of Seagrove Beach and the beach communities along 30A, including Grayton Beach and Seaside.

** Census Designated Place

1.12 Stormwater Infrastructure Inventory

Local community stormwater systems consist of drainage ditches, storm sewers, retention ponds and other facilities constructed to store runoff or carry it to a receiving stream, lake, ocean, or other waterbody. Other man-made features include yards and swales that collect runoff and direct it to the sewers and ditches. When most of these systems were built, they were typically designed to handle the amount of water expected during a 10-year storm. Larger storms overload them, and the resulting backed-up sewers and overloaded ditches produce shallow flooding. Another urban drainage problem occurs in the areas protected by levees. Being in floodplains, they are flat and do not drain naturally, especially when a levee blocks the flow to the river. To drain these areas, channels have been built and pumps installed to mechanically move the water past the levee. Often, these man-made systems do not have the capacity to handle heavy rains or intense storms.

Another challenge with stormwater infrastructure is related to recordkeeping. It is not uncommon for stormwater data to be incomplete in most jurisdictions and completely lacking in others. Quality of data differs from jurisdiction to jurisdiction; some are in GIS formats, while others are paper maps or as-builts that represent the infrastructure at a macroscale level. The condition of the assets may be lacking, and the maintenance history may not be available either. Stormwater assets may have been installed with no records, especially in rural areas, farm fields, and private property.

Walton County passed Ordinance No. 2008-06 that prohibits unauthorized discharges into storm drains or ditch systems. In addition, the Public Works Division is currently running a continuous public awareness campaign aimed at encouraging the adoption of best management practices (BMPs) for managing stormwater runoff. This initiative targets both the business community and the residents of Walton County.

To address the issue of flooding, Walton County has implemented several measures along the years, such as:

- Drainage Systems: The county has invested in the development and maintenance of drainage systems, including ditches, canals, and retention ponds, to manage stormwater runoff and reduce flood risk.
- Floodplain Management: Walton County has adopted floodplain management regulations and participates in the National Flood Insurance Program (NFIP) to encourage responsible development in flood-prone areas.
- Elevation Standards: New construction projects within flood zones are required to adhere to specific elevation standards to minimize potential flood damage.

- Emergency Response: The county has established emergency response plans to assist residents during flood events, including evacuation procedures and the provision of emergency shelters.

Key stormwater assets for the HUC and Walton County are indicated in **Error! Reference source not found.** and **Error! Reference source not found.**, respectively. Stormwater structures and management processes in the county consist of stormwater outfall, water wells, weir, pollutant control boxes, inlets catch basins, pipes culverts, ditch conveyance swales, structures, pipes and open conveyance.

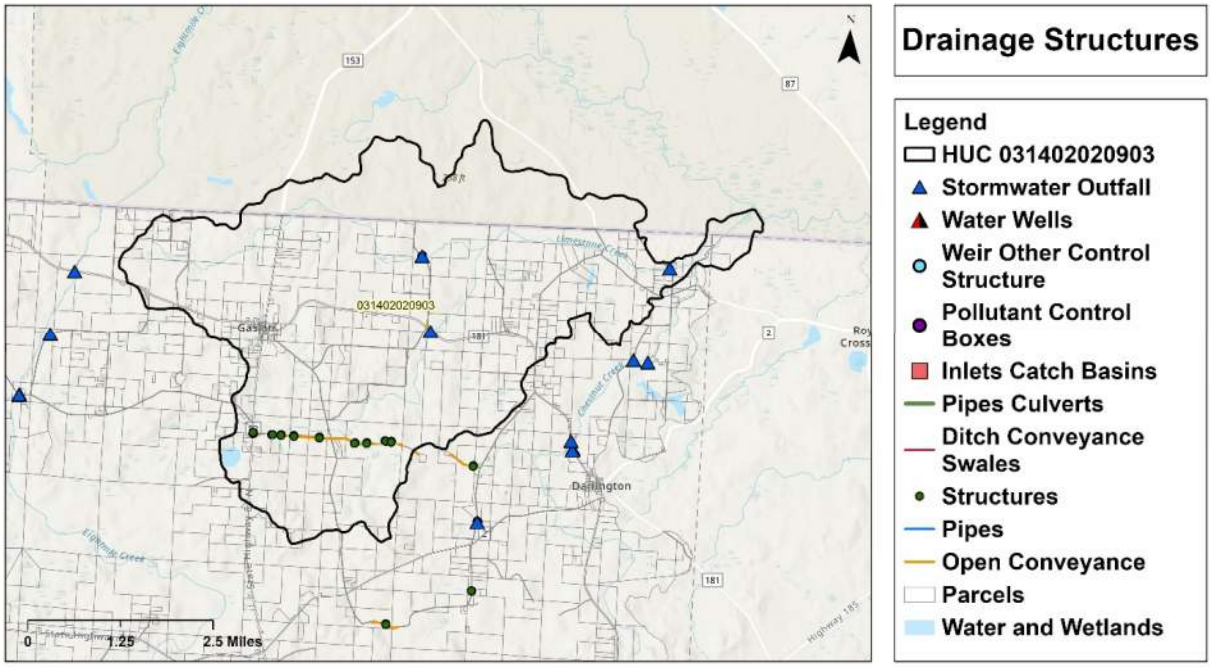

Figure 27. Stormwater Infrastructure for the HUC 031402020903. Processed by FAU.

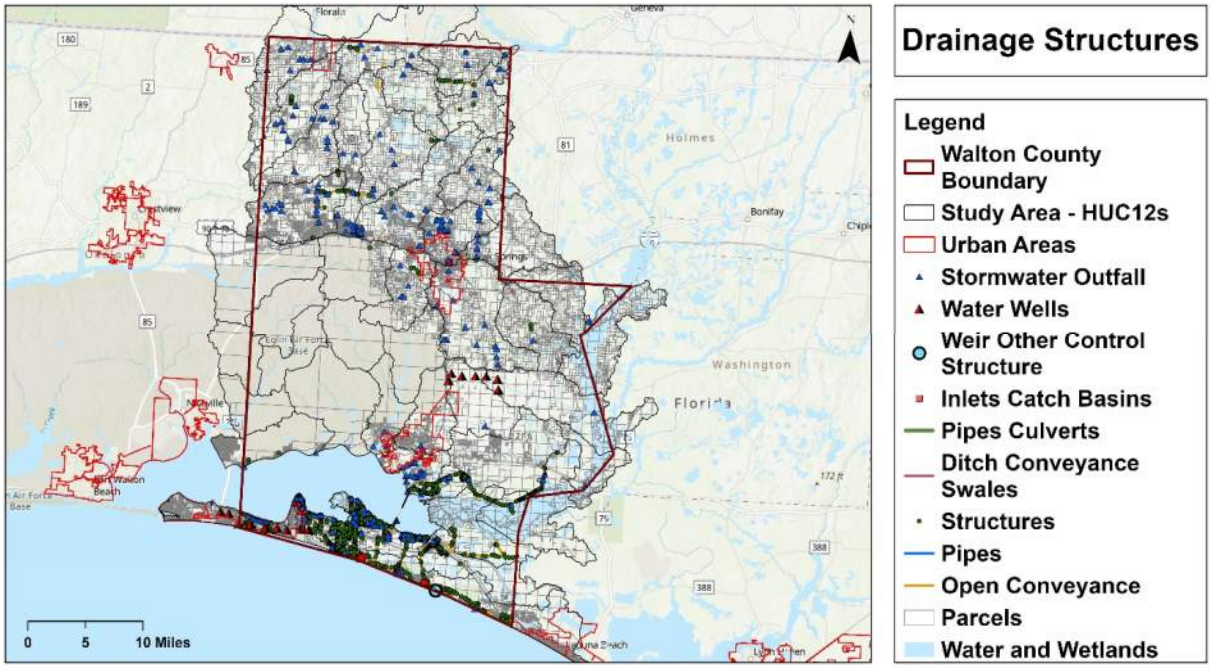

Figure 28.Stormwater Infrastructure for Walton County. Processed by FAU.

Although nature-based infrastructure might be installed, it is not certain. The stormwater system must maintain compliance with the stormwater regulations, which requires record-keeping, policy development, inspections and maintenance. The goals of such stormwater management may include:

- Best landscape practice;
- Control car washing contribution to pollution;
- Enforce the Stormwater Pollution Prevention Plan (SWPPP) by site evaluation, assessment, erosion and sediment controls, preventive maintenance, certification and inspection reporting for construction sites and city planning;
- Implement a hazardous material elimination system;
- Eliminate illicit dumping;
- Proactive and reactive catch basin inspections and maintenance;
- Street sweeping to control debris;
- Maintain swales to help prevent stormwater pollution flooding.

1.13 Data Gaps

FAU has developed comprehensive databases to address the information needed for the vulnerability assessment. These are included in **Error! Reference source not found.**. The data

can be used to model the impacts of flood routing during the storm of interest. As a result, the modeling pieces (discussed in Chapter 2) will include the following:

- Flood response model results (Cascade 2001)
- Flood risk/hazard mapping
- Vulnerability assessments to identify areas of concern for future repetitive losses

There is only one data gap for the area – existing stormwater infrastructure records are incomplete. However, for the purposes of this plan, this data gap does not limit the findings as there are two scales: 1) the sub-watershed level and 2) community hotspots. A neighborhood level vulnerability assessment will require the local infrastructure inventory.

Table 6. List of datasets collected by FAU as of List of datasets collected by FAU for the project (12/20/2020)

2.0 ASSESSMENT OF VULNERABLE AREAS

Defining flood risk due to compounding hydrographic influences is the central concern of this WMP. Modeling and assessment of vulnerability focused on the combination of a high-water table, heavy rains, and impervious conditions that can lead to localized nuisance flooding events. Through a previous survey with local officials, the number of days of continuous nuisance flooding that the public will tolerate before that flooding is considered destructive is about 4 days (E Science 2014).

For a large study area, small parts may actually be at risk. The point is to identify where further study might be needed. A screening tool accomplishes this goal applied to the sub-watershed scale to designate areas that are susceptible to periodic flooding events. Utilizing the information collected and analyzed in Chapter 1, an analysis of flood vulnerability can be performed.

2.1 Historical and Existing Challenges

Walton County has faced various historical and existing challenges as well as natural hazards over the years. Some of these include:

- Hurricane and Tropical Storms: being situated along the Gulf Coast, Walton County is vulnerable to hurricanes and tropical storms, which can lead to damage to the built and natural environment, as well as poses risks to human and wild life.
- Coastal Erosion: The county's coastline is subject to erosion due to natural processes and human activities. Erosion can lead to the loss of beaches and threaten coastal structures and properties.
- Flooding: heavy rainfall, storm surges from hurricanes, and other factors can cause localized flooding, particularly in low-lying areas. Flood events can disrupt daily life, damage property, and impact transportation.
- Water Quality and Quantity: as in many coastal areas, managing water quality and maintaining an adequate water supply are ongoing challenges. Pollution from stormwater runoff and other sources can affect water quality, and groundwater resources need to be carefully managed to sustain the growing population.
- Wetland Loss: The county's wetlands face the threat of degradation and loss due to urban development and other human activities. Protecting these essential ecosystems is vital for maintaining biodiversity and mitigating flood risks.
- Urbanization and Development: Balancing the demand for development and growth with the preservation of natural habitats and resources is a persistent challenge. Unplanned urbanization can lead to habitat destruction, increased runoff, and exacerbate flooding risks.

- Land Use and Zoning: Proper land use planning and zoning are essential to address issues related to population growth, infrastructure development, and natural hazard mitigation. Ensuring responsible development practices can help minimize risks.
- Invasive Species: Like many regions, Walton County faces the threat of invasive plant and animal species. These invasive species can disrupt local ecosystems, negatively impacting native flora and fauna.
- Sea-Level Rise: With rising sea levels due to climate change, coastal communities like Walton County's coastal areas are at greater risk of inundation and storm surges during extreme weather events.

The fast growth of the population and urban development in the coastal areas of the county exacerbates effort to protect open space for land percolation of water. While regulations are in place to reduce the influx of stormwater, the challenges will continue with development.

2.1.1 Existing Management Efforts in the Watershed

The county is under Northwest Florida Management District (NWFMWD) jurisdiction, which covers the Florida Panhandle region. The NWFMWD is responsible for managing and protecting water resources in its designated regions, which includes issues related to water supply, water quality, flood control, and natural resource conservation. Local governments have local stormwater utility infrastructure and planning/policy tools to reduce future flood potential. Most of the major projects to date have been focused on addressing the water quality issues and flooding due to extreme rainfall.

2.1.2 Critical Target Areas Identification

By modeling the HUC 031402020903 sub-watershed flood response to a series of rainfall events (plus king tides), and further classifying flood risk as the probability of inundation, it is possible to identify critical target areas. These areas are particularly vulnerable to flooding and are subject to further study through a scaled-down modeling approach. The screening tool is first applied at the greater watershed level to provide an initial risk assessment focused on the hydrologic response to a rainfall event given the unique characteristics and features of the sub-watershed or study area. The process is discussed later in Section 2.2 with results presented in Section 2.3.

2.1.3 Potential Preservation Areas

Walton County boasts several areas with high biodiversity value. These areas include the unique coastal dune lakes, which support diverse ecosystems and contribute to water quality along the coast. Wetlands are crucial habitats that provide refuge for a variety of plant and animal species

while acting as natural water filters. State parks like Topsail Hill Preserve and Grayton Beach State Park are valuable conservation areas with diverse coastal ecosystems. Additionally, preserving the Choctawhatchee River Basin is essential for the biodiversity of the region.

2.2 Vulnerability Maps

2.2.1 Screening Tool

The screening tool utilizes topographic data from various sources (Section 1.1), water table elevations (Section 1.2) and surface water gauges (Section 1.3) downloaded from the NWFWMD DBHYDRO website, tidal information for coastal areas obtained from the NOAA Current & Tides website (Section 1.3), soil maps obtained from the USDA (Section 1.4), and another key dataset as described previously in Chapter 1. The design storms are discussed in Section 1.6. The reason this is critical is that to do any modeling (as required by the CRS program), a screening tool should be used to identify regions with a high risk of inundation based on multiple collected datasets and hydrological models. **Error! Reference source not found.** shows how the GIS layers interface in the tool and how they are combined for spatial analysis.

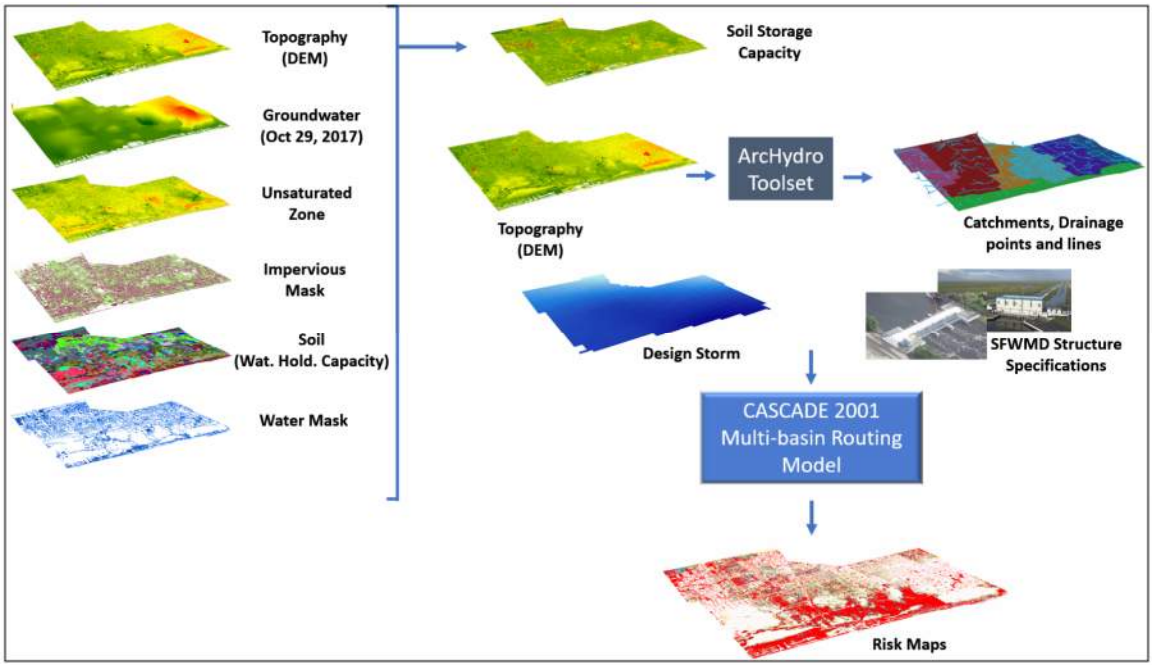

Figure 29. Screening tool methodology for creating flood risk maps.

The model chosen for this screening tool is Cascade 2001, which is a multi-basin hydrologic/hydraulic routing model developed by the SFWMD. The model permits the investigator to run different storm events to determine flooding scenarios. The boundaries are

critical for basin studies and must be chosen carefully. The following data layers collected in the prior section are processed to develop the input files for Cascade 2001:

- Topography
- Soils
- Development intensity
- Groundwater elevations
- Surface water/Outlet locations

The software creates a glass box where water rises to a certain level and then decreases. Running the simulation requires defining the basin (HUC or sub-HUC) and input of the following data:

- Area
- Portion of area above a given elevation
- Initial groundwater stage
- Longest travel time for the runoff to reach the most distance point of discharge
- Ground storage as estimated from the USDA gridded National Soil Survey Geographic Database (gNATSGO)

  Ground storage ≈ (Water holding capacity) × (Surface elevation – GW elevation)
  = 2 × (AWS for a soil layer of 0-150 cm) / 150cm × (Surface elevation – GW elevation)

- Available water storage (AWS) for a soil layer of 0-150 cm
- Average amount of precipitation that can be stored in the soil layer

The output from the model is an elevation surface that can be used to develop a flood map for the study area (**Error! Reference source not found.**), which shows the spatial distribution of probabilities of flooding during the modeled 1-day 100-year storm event.

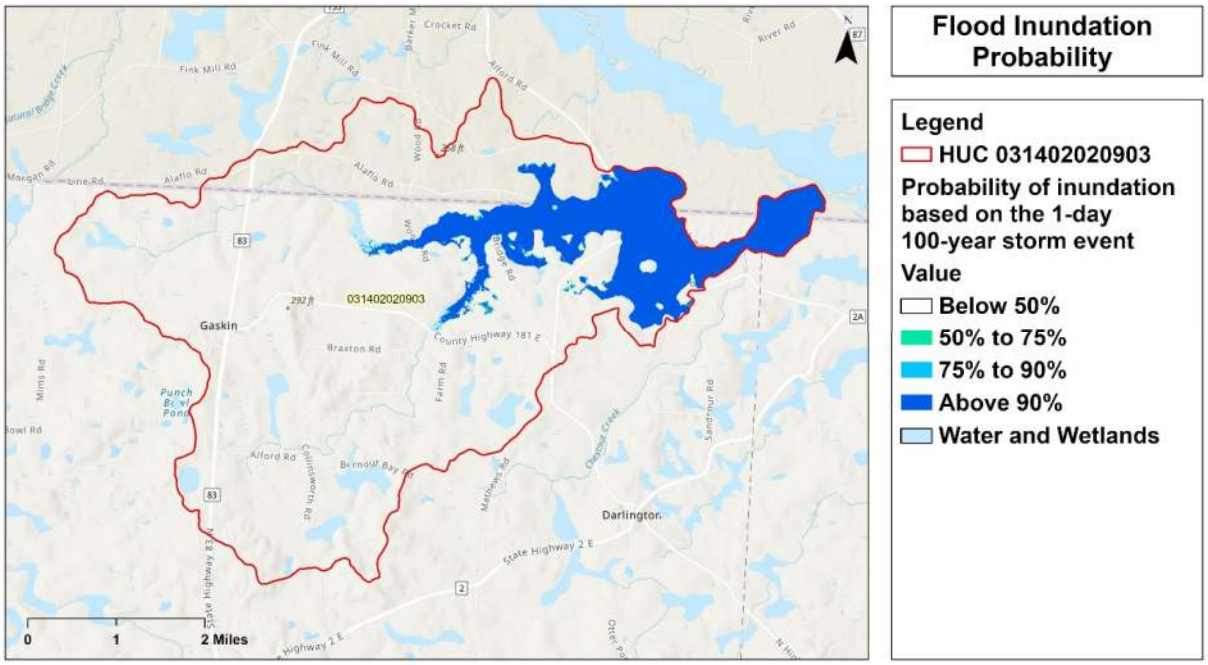

Figure 30. Probability of flood risk map during the modeled 1-day 100-year storm event for the HUC 031402020903, processed by FAU.

2.2.2 Identification of Vulnerable Areas

Given these assumptions and the Cascade 2001 outputs, the goal of this methodology is to produce a spatially-temporally quantified understanding of nuisance-destructive flood potential in the study area given observed values. Risk is a function of compounding geo-hydrological features, namely, surface water, groundwater, topography, build-out, and time of year. A GIS-based algorithm and spatial interpolation generated layers of the greatest observable hydrographic surfaces. These outputs were then compared with high resolution topographic LiDAR data to develop digital elevation models that reflect the observed risk landscape. These models can then be combined into Cascade 2001 to produce vector and volume information, in combination with soils, vegetation and impervious surfaces, allowing the observed model outputs to be extrapolated into a more predictive context.

To evaluate flood vulnerability at this scale, the analysis starts with a binary flooding surface (0 = below 50% chance of flooding; 1 = above 50% flooding) based on output from the screening tool for a specified design storm. Next, attributes of that raster based on "VALUE = 1" query are extracted using *Extract by Attributes* tool. Then the *Batch Project* tool was used to map critical facilities data to the common coordinate system (NAD83 UTM Zone 17N), unit = meters. Then a field was added using *Add Field* for [PriorityTier] = assigned Tier #1-4 value from the DOR codes and [Area_sqmeter]. The critical facilities layers were then merged into a single layer to calculate

the polygon geometry for [Area_sqmeter] using the *Merge* tool. Next, *Zonal Statistics as Table* is used to calculate the SUM of flooded values ("VALUE = 1") within each critical parcel. Output table has fields for SUM (i.e., total # of flooded pixels per critical parcel) and AREA in map units of square meters (since each pixel in the flooding surface has a cell size of 3-meters by 3-meters, each area is equal to the SUM value multiplied by 9 m^2). Using the *Join Field* tool, the SUM and AREA fields are joined to the merged critical facilities layer based on a key attribute, first renaming these fields for clarity (e.g., AREA_FLOODED_3d25y). Once all field data is included, the next step involves using *Export Table* to export the dataset as a CSV file. Note that non-flooded parcels have zero flooded area, so they receive a <Null> value from the zonal statistics tool. To replace null values with zeros, we use *Calculate Field* in the attribute table along with the following Python expression (replacing the respective field name): "0 if !AREA_FLOODED_3d25y! is None else !AREA_FLOODED_3d25y!". Next, the CSV file is saved as an Excel Workbook (.xlsx). The Range is converted to an Excel Table, and the columns are rearranged in the desired order. Finally, the "percent-flooded" columns are calculated as follows:

- PCT_FLOODED_3d25y = ([@[AREA_FLOODED_3d25y]]/[@[TotalArea_sqmeter]])*100
- PCT_FLOODED_1d100y = ([@[AREA_FLOODED_1d100y]]/[@[TotalArea_sqmeter]])*100

After this calculation, the table is sorted to show the higher priority tiers and higher percent-flooded values first. To reduce the number of critical facilities shown in the final table, a filter was created to show only critical facilities with 10% or more flooded area in the parcel during both storm events. Records with duplicate parcel ID numbers were removed from the table. The results of this procedure are discussed in Section 2.4 of this document.

With respect to dams and levees, for purposes of the NFIP, FEMA only recognizes systems that meet, and continue to meet, minimum design, operation, and maintenance standards that are consistent with comprehensive floodplain management criteria. The Code of Federal Regulations, Title 44, Section 65.10 (44 CFR 65.10) describes the information needed for FEMA to determine if a levee system reduces the risk from the 1% annual chance flood. FEMA has accredited levees and Provisionally Accredited Levees (that have a specified timeframe to obtain the necessary data to confirm the levee's certification status). If a levee system no longer meets Section 65.10, FEMA will de-accredit the levee system and issue an effective FIRM showing the levee-impacted area as a SFHA. FEMA coordinates its programs with USACE, who may inspect, maintain, and repair levee systems. USACE has authority under Public Law 84-99 to supplement local efforts to repair flood control projects that are damaged by floods. Like FEMA, USACE provides a program to allow public sponsors or operators to address levee system maintenance deficiencies. Failure to do so within the required timeframe results in the levee system being placed in an inactive status in the USACE Rehabilitation and Inspection Program. Levee systems in an inactive status are not

eligible for rehabilitation assistance under Public Law 84-99. There are no levees/dams listed in the sub-watershed study area.

2.3 Modeling Results

Error! Reference source not found. to **Error! Reference source not found.** are a series of maps that depict risk of flooding in the basin based on the following scenarios:

1. 3-day 25-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
2. 1-day 100-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
3. 1-day 10-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)
4. 1-day 5-year storm event. Note a 2.97 ft King Tide was also included based highest tide from NOAA tidal gauge stations (**Error! Reference source not found.**)

In all storm event scenarios, a substantial volume of flooding is observed at the entrance of the creek within the HUC, following its natural flow path. As this basin is not connected to the ocean and its altitude is above 20 feet, the HUC is expected to remain unaffected by sea level rise, therefore SLR scenarios were not computed.

The design storm simulation determined that approximately 14.61% of the HUC total area or 3.30 mi^2 has a probability of inundation above 50% for a 3-day 25-year design storm. For comparison, approximately 14.32% of the HUC's total area, or 3.23 mi^2 would be expected to be inundated during a 1-day 100-year design storm. Approximately 13.91% of the HUC's total area, or 3.14 mi^2, would be expected to be inundated during a 1-day 10-year design storm. Finally, approximately 13.91% of the HUC's total area, or 3.14 mi^2, would be expected to be inundated during the 1-day 5-year storm. **Error! Reference source not found.** compares the four storm events.

Table 7. HUC 031402020903 expected inundated area by storm event.

Storm Event	Area with probability of inundation below 50% (Sq Mi)	Area with probability of inundation above 50% (Sq Mi)	Area with probability of inundation below 50% (%)	Area with probability of inundation above 50% (%)
3-day 25-year	19.28	3.30	85.38%	14.61%
1-day 100-year	19.35	3.23	85.68%	14.32%
1-day 10-year	19.44	3.14	86.08%	13.91%
1-day 5-year	19.44	3.14	86.08%	13.91%

2.4 Risk and Vulnerability

The screening tool modeling exercise from the prior section identified areas within the communities that are vulnerable to flooding. Higher priority concerns should be those properties or assets that are considered essential and need to be kept in service during a flooding event. All other improvements are local. To help with prioritization, the following is suggested:

- Tier 1 - Critical facility protection (water/sewer utilities, public safety, hospitals, schools, power, shelters)
- Tier 2 - Essential facilities (groceries, pharmacies, roadways)
- Tier 3 - Economic centers (protecting jobs)
- Tier 4 - At risk communities
- Tier 5 - Other urban/suburban property
- Tier 6 - Agriculture/public property/vacant/undeveloped

Error! Reference source not found. outlines the priority of land use based on DOR land use codes from the property appraiser's office and assigns an associated priority level to each parcel. Note that for residential property, identifying at-risk communities (income, age, disability, health) requires a further drilldown to the neighborhood level (i.e. wealthy neighborhoods with few older,

poor health individuals would have a lower priority than at risk communities, which generally have lower value housing and denser development). In the latter case, more people are impacted, and those people have less ability to mitigate risk. Based on these priorities, the relative risk priority DOR land use codes were evaluated based on a scale of 1 to 6, where 1 is higher priority (more vulnerable) and 6 is the least priority (least vulnerable).

Table 8. Priority of Land Use based on (DOR) land use codes. Processed by FAU.

Having assigned the risk priority from 1 to 6 in the DOR codes and the percentage of the parcel that floods during the applicable design storm, properties that are more critical to the function of the community can be identified. The methodology is to first convert the DOR code priority tier to its inverse scale by the following equation:

Consequence of risk factor = 7 – DOR Code Priority Tier

The flood risk factor from the screening tool is interpreted based on flooding probability. We take all parcels in tiers #1-4 that have a greater than 50% chance of flooding during a particular design storm and calculate the percent of the parcel that would flood during that event. The percentage is converted to a 6-point scale termed as the Flood Risk Factor, shown in **Error! Reference source not found.**.

Table 9. Flood Risk Factor Classification.

Percent of Parcel Flooded	Flood Risk Factor
90-100%	6
80-89%	5
70-79%	4
60-69%	3
50-59%	2
<50%	1

The priority is further developed by assigning 75% of the importance to the consequence of flooding and 25% importance to flood risk, or three times the importance to the consequence of flooding to come up with a composite score as follows:

Flood Risk Factor × 25% + Consequence of Risk Factor × 75% = Composite Score

Example: 1 × 25% + 6 × 75% = 4.75

Those higher priority properties that received the higher composite score are where the mitigation strategies and financial resources should focus first.

2.4.1 Results

Error! Reference source not found. and **Error! Reference source not found.** depict the HUC 031402020903 sub-watershed priority of land uses showing the critical facilities that should receive priority. The first map (Figure 35) exclusively displays critical facility parcels within the HUC without any flooding. The second map (Figure 36) overlays critical facilities onto the 1-day 100-year storm event scenario. **Error! Reference source not found.** is a mosaic showing critical facilities overlaid in the 1-day 100-year storm event for the whole county.

Additionally, **Error! Reference source not found.** illustrates the composite score based on 1-day 100-year storm event for the HUC, which is the result of the calculations explained above, pinpointing parcels that should be prioritized. It considers only parcels classified as 1 to 4 tiers, and within the 50% probability of inundation area. Lastly, **Error! Reference source not found.** is a mosaic showing the results for composite score overlaid in the 1-day 100-year storm event for the coastal area of Walton County. As the subwatershed is not coastal, the results based on 5 ft. SLR + 1-day 100-year storm event were not computed for the basin.

Please note that the composite score results display outcomes exclusively for parcels within the flooding path area. Consequently, for parcels outside this flooding path, the composite results will be null. The composite score combines the flooding path area with the land use priority results to identify the most vulnerable areas deserving of priority.

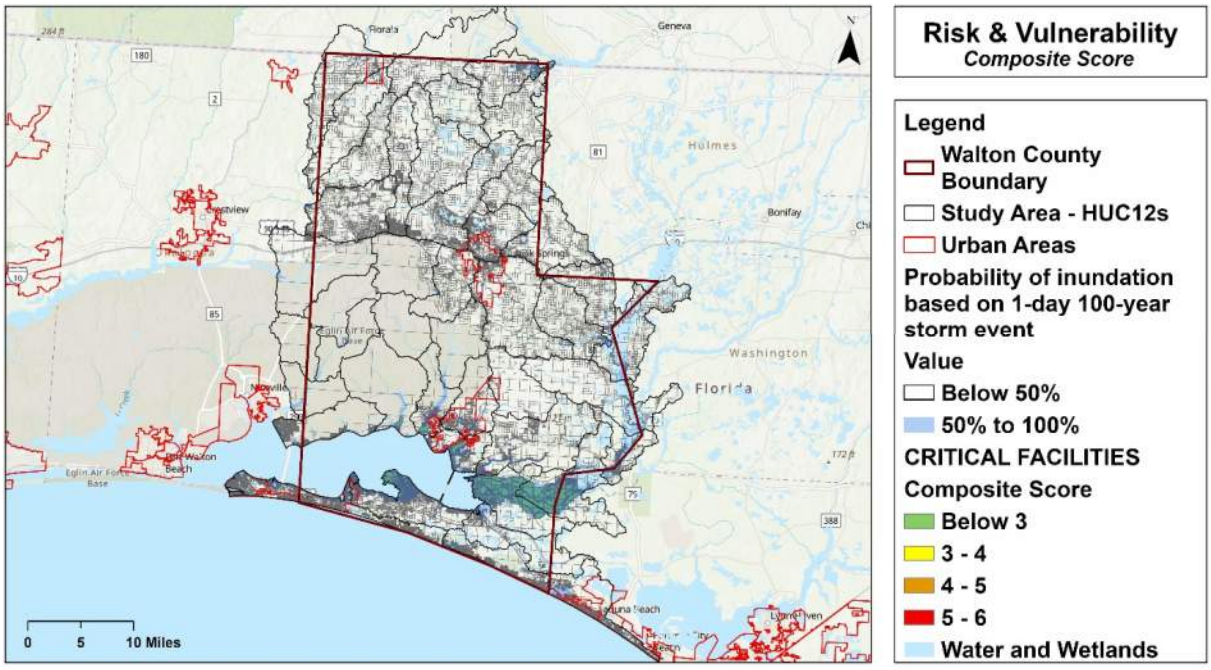

Figure 39. Walton County (mosaic) - Composite Score Risk map overlaid on the 1-day 100-year storm event probability of inundation. Processed by FAU.

Please note that due to the scale of the map, the composite score layer is not properly visible in this map.

2.4.2 Solutions

Chapter 5 of the Watershed Master Plan for Walton County describes a list of possible gray and green stormwater strategies to combat flooding that can be implemented as solutions for the county. The same solutions can also be applied at the HUC level, including HUC 031402020903. A summary of these flood mitigation strategies is listed in **Error! Reference source not found.**. For more detailed information, please see Chapter 5-5.3 (Solutions).

Table 10. List of possible gray and green stormwater strategies to combat flooding

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Green	Rainwater harvesting	Local, small scale, easily implemented in developed areas	Protects property, treats runoff	Under $5,000	Limited volume disposed of, so many are needed, maintenance

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Pervious paving	Parking lots, patios, driveways, anything except paved roads due to traffic loading	Reduces roadway and parking lot flooding	$10-20/sf, requires bumpers and sub-base to maintain paver integrity	Must be maintained via vacuuming or the perviousness fades after 2-3 years
Green	Detention	Common for new development, but difficult to retrofit; limited to open areas	Removes water from streets, reduces flooding	$200K/ac	Land availability, maintenance of pond, discharge location Uses up land that could otherwise be developed
Gray	Exfiltration Trench	Any low-lying area where stormwater collects and the water table is more than 3 ft below the surface; densely developed areas where retention is not available, roadways	Excess water drains to aquifer, some treatment provided	$250/ft	Significant damage to roadways for installation, maintenance needed, clogging issues reduce benefits
Gray	Central sewer installation	All areas where there are septic tanks. Mostly a water quality issue	Public health benefit of reducing discharges to lawns, canals, and groundwater from septic tanks	$15,000 per household	Cost, assessments against property owners, property rights issues
Green	Flood prone property acquisition	Regional agency - could be any low-lying areas	Removes flood prone areas from risk	$2K-$100K/ac depending on whether it is already developed	Difficult to implement if occupied, issues with willing sellers, cost, lack of funds for acquisition
Gray	Pump stations	Any low-lying area where stormwater collects, and there is a place to pump the excess stormwater to such as a canal; common for developed areas	Removes water from streets, reduces flooding	Start at $1.5 to 5 million each, number unclear without more study	NPDES permits, maintenance cost, land acquisition, discharge quality

Strategy Class	Implementation Strategy	Applications	Benefits	Cost	Barriers to Implementation
Gray	Armored sewer systems	Any area where gravity sanitary sewers are installed	Keeps stormwater out of sanitary sewer system and reduces potential for disease spread from sewage overflows	$500/manhole	Limited expense beyond capital cost
Gray	Sea walls	Barrier islands and downtown coastal areas	Protects property	$1200/ft	Private property rights, neighbors
Policy	Changes in land use	Applicable universally	Achieves flood risk mitigation by adjusting permitted land use	Low but may incur private property rights conflicts and litigation	Private property rights conflicts and litigation
Gray	Roadway base protection	Low-lying areas, coastal communities	Protects roads and access routes	$1 million per lane-mile	Cost, adjacent properties become uninsurable
Policy	Enhanced elevation of buildings	Developers would implement this for new construction	Reduced flood risk	Varies	Potential issues with building structure or latticework, and existing homes that are not elevated

2.4.3 Impacted Adjustment Areas

In the evaluation of flood risk management strategies within the framework of the National Flood Insurance Program Community Rating System (CRS), the concept of impact adjustment plays a pivotal role in determining the extent to which CRS-credited activities or elements influence the vulnerability of a community's Special Flood Hazard Area (SFHA) and the structures located within it. It is important to note that while the usual results of impact adjustment are related to the SFHA area, in this specific analysis, it was used 1-day 100-year storm event inundation area performed by FAU instead.

In this context, the following table presents a breakdown of the impact adjustment calculations for a 1-day 100-year storm event inundation. The values are expressed in acres and depict the areas of interest as well as the deductions considered in the evaluation process.

The outcomes of these calculations provide valuable insights into the impact adjustment scenarios:

With ALL State Lands:

This scenario reflects the remaining inundation area after accounting for deductions A, B, and C. It represents the effect of CRS-credited activities without considering the influence of state lands in managing flood risks.

With NO State Lands:

In this case, the remaining inundation area is determined by considering all deductions, including state lands (both open space and not open space– see **Error! Reference source not found.**).

These calculations highlight the dynamic nature of impact adjustment within the CRS framework. By accurately gauging the influence of individual elements, the system ensures that credit allocations align closely with a community's efforts in flood risk mitigation.

Table 11. Impacted Adjustment Areas for HUC 031402020903. Processed by FAU.

AREAS	**ACRES**
HUC-12 Sub-watershed: 031402020903	14454.51
All of the 1-day 100-year storm event inundation	**2069.91**
Subtract	
A. Bodies of Water in 1-day 100-year inundation > 10 acres	0.00
B. Federal Land in 1-day 100-year inundation > 10 acres	0.00
C. Reservation/Tribal Land in 1-day 100-year inundation > 10 acres	36.60
D. State Land in 1-day 100-year inundation > 10 acres that is open space	0.00
E. State Land in 1-day 100-year inundation > 10 acres that is NOT open space	0.00
The remainder is either:	
With ALL State Lands: All of the 1-day 100-year inundation minus (A+B+C) or	2033.31
With NO State Lands: All of the 1-day 100-year inundation minus (A+B+C+D+E)	2033.31

2.4.4 Repetitive Loss Property Map

A Repetitive Loss (RL) property is a building that has had two or more loss or damage due to a specific hazard, such as floods, hurricanes, or other natural disasters, over $1,000 each, paid by the National Flood Insurance Program (NFIP) within any ten-year period since 1978. There are more than 122,000 RL properties in the nationwide (FEMA, 2005).

These data are essential for assessing the vulnerability of certain areas to recurrent losses and for developing strategies to mitigate the risks. However, due to privacy concerns, the data cannot be openly shared with the public. For this reason, the data were converted into a hot spot analysis map. These maps, instead of identifying the specific location of the repetitive loss properties, highlight clusters of repetitive loss claims and areas where the probability of repetitive losses is higher than would be expected by random chance. In other words, it helps pinpoint locations that

have a higher concentration of properties prone to repetitive losses. **Error! Reference source not found.** indicates the results from hot spot analysis in point data, showing aggregated counts, and raster data, showing the estimated probability of repetitive loss.

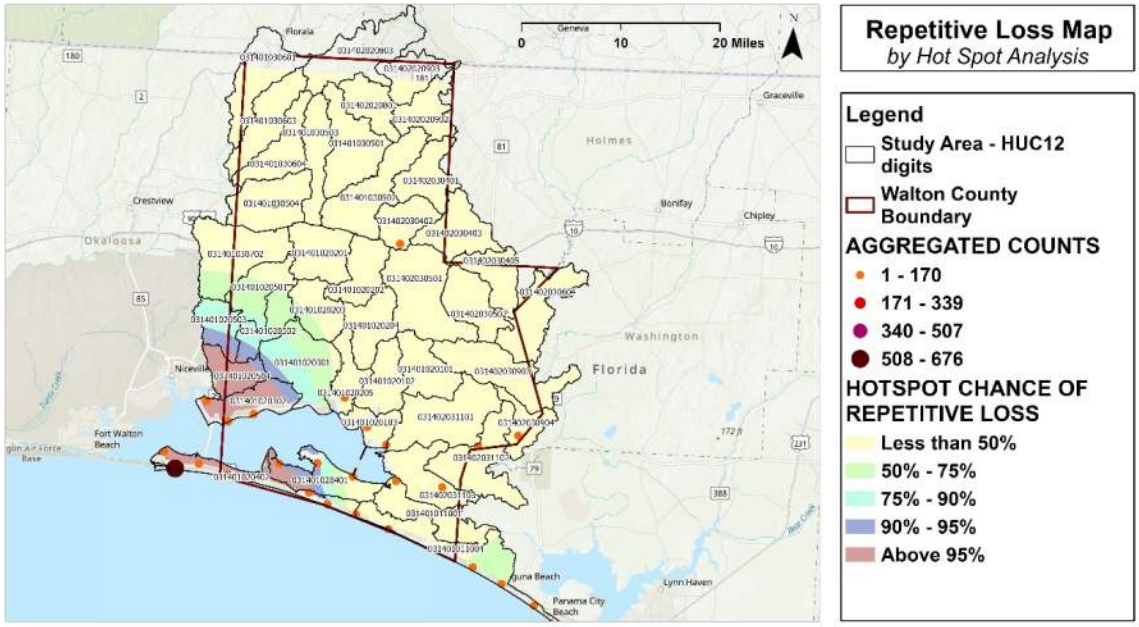

Figure 40. Repetitive Loss map for Walton County by Hot Spot Analysis. Processed by FAU.

2.4.5 Priority Projects

Although the basin does not features a significant amount of developed land, it is possible to note some parcels falling within the flood zone. In terms of priority for land use, there are parcels in tier 2 (roads) that need some attention, and tiers 4 and 5, signifying a lower priority for intervention. Although there are a few parcels classified as tier 1 of priority of land uses, there are not within the flood.

Examining the composite score, 14 parcels as total presents results, therefore, are within the flooding zone. Among them, three are within the score range of 5-6, and all of them are roads (Al County Road 10, Jasmine Drive, Cook Road), representing the highest priority for intervention. Furthermore, there are four parcels within the score range of 4-5, all of which are also roads (Woods Road, Penn Williams Road, Beck Bridge Road, Oak Grove Road). In the score range of 3-4, there are four parcels, all classified as mobile homes, and within the score below 3, there are 3 parcels, all of which are also mobile homes.

It is also important to mention that a good portion of the basin has not been included in the priority land use analysis and, consequently, in the composite score calculation. This omission is due to the project's reliance on land use data solely from Florida, and the basin has a portion on Alabama

as well. The categories of land use maps in Alabama would be different, making it impossible to match the data from two different databases in different states. As a result, there is a slight possibility that there may be priority projects on the Alabama side of the basin of which we are not aware.

X.0 EXECUTIVE SUMMARY

The goal of the appendices to the watershed plan are to outline the issues associated with the individual HUC12s that contribute or impact the community's flood vulnerability and there for its flood protection efforts. Floodplain analysis includes developing a watershed model and identifying associated inundation polygons. It builds upon information generated from the watershed evaluation so that planning and management decisions can be formulated.

This appendix describes the issues and modeling associated with one of the HUC12s that affects Walton County. In developing the County-wide plan, this HUC 12 was analyzed so as to determine how it brings or removes floodwaters from the County. For the NFIP process the goal is to analyze all communities at the HUC12 level. From a community perspective the HUC12 is less useful to residents than a community-wide plan. Hence in all cases the HUC12 results were mosaicked into the community-wide plan. Details can be found in the HUC12 appendices, some of which were brought into the community plan.

To reduce redundancy, information of the plans, ordinances, policies and regulations were rolled up to the community-wide plan and will not be repeated in the appendices. Likewise, the community wide mapping was parced for HUC12 use.

1.0 WATERSHED CHARACTERIZATION

In this section, key aspects of the watershed are characterized. This is important for later being able to identify the most vulnerable areas and to mobilize resources to implement an action plan. Understanding the characteristics of the watershed involves gathering existing information and data sets from previous planning efforts. It is important to note that this step is iterative and ongoing as new data are generated and projects are implemented and monitored.

To assess the historical and current conditions of the study area, the following existing data sets that characterize the physical and natural features of the watershed were obtained for each HUC-12 subwatershed in the study area:

- Topographic data (LiDAR)
- Relevant waterway locations
- Groundwater levels
- Soils data
- Land uses including vacant land, wetlands, impervious, etc.
- Precipitation records
- Catchment delineations for flood routing

In addition, the FEMA flood maps must be obtained, and the storm of interest must be identified for screening purposes (1-day, 2-year, 5-year, and 100-year events as well as the 3-day 25-year storm event to achieve class 4 in the CRS Manual). In developed areas, many sources of data are already available – the key is putting the key datasets in a format that can queried for screening to identify the priority areas of the watershed. Table 6 is a summary of datasets available at cwr3.fau.edu that were used to construct this plan.

This watershed master plan is a drilldown of the larger Walton County TMDL region, which involves 42 HUC 12-digit sub-watersheds (**Error! Reference source not found.**). **Error! Reference source not found.** shows Walton County Drainage Network and the location of urban areas (cities and towns). In **Error! Reference source not found.**, the HUC-12 (031402030401) is highlighted among all the HUCs to help identifying its location. (Figure 3).

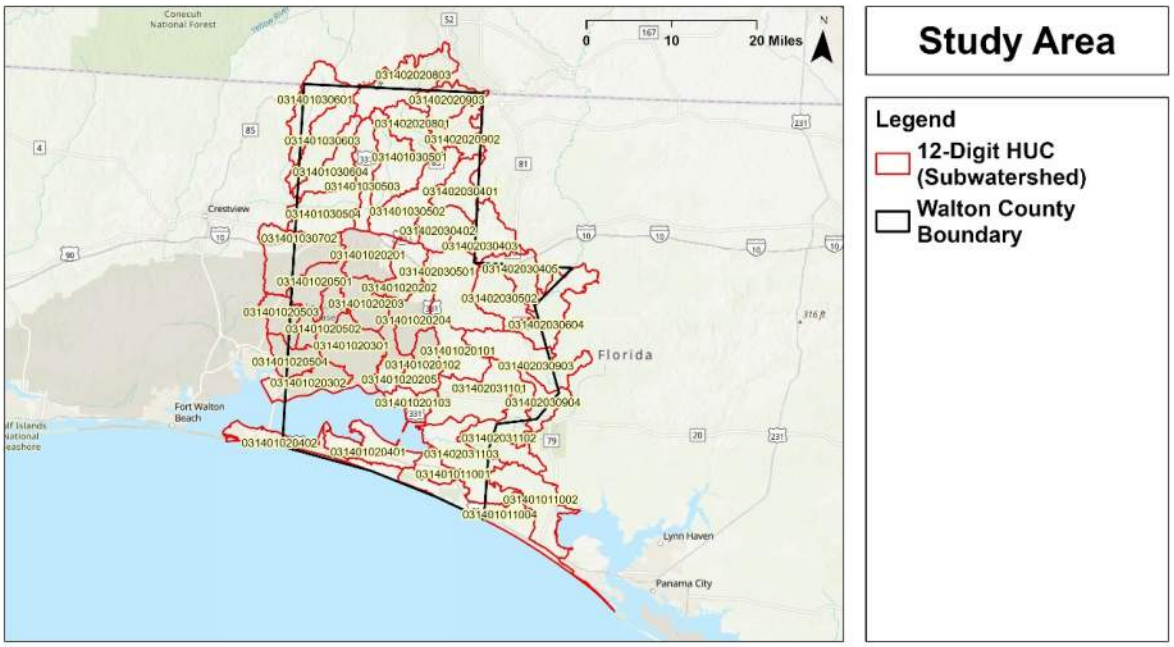

Figure 1. Walton County and all HUCs 12-digit subwatershed, processed by FAU.

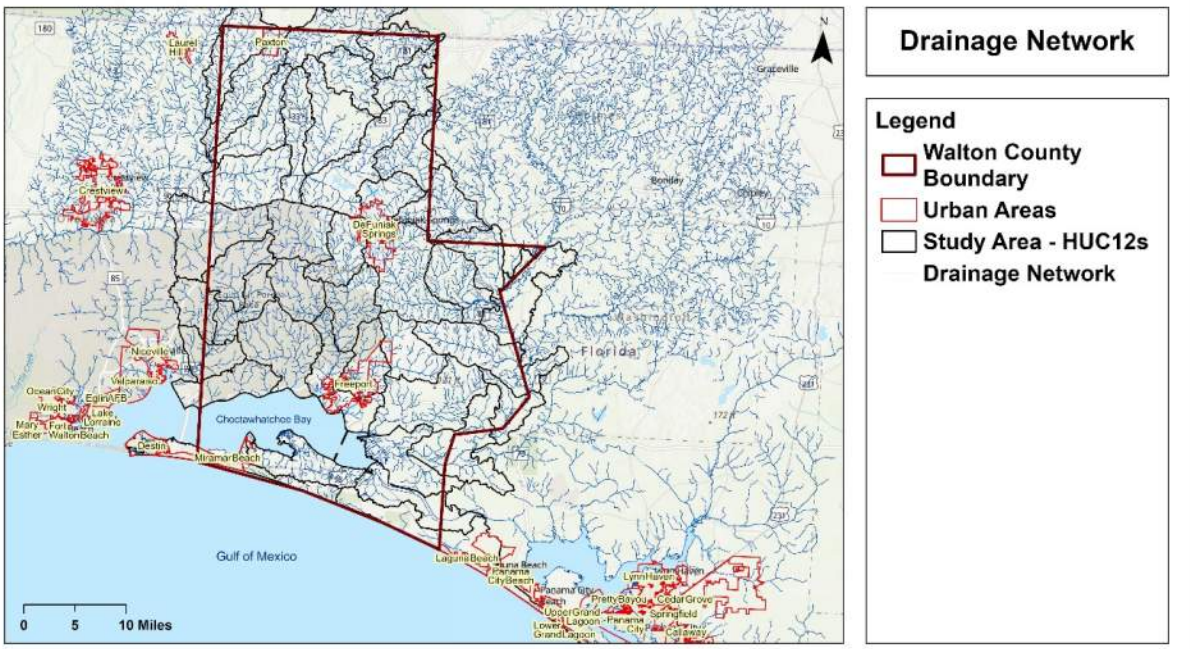

Figure 2. Walton County Drainage Network and urban areas (cities and towns), processed by FAU.

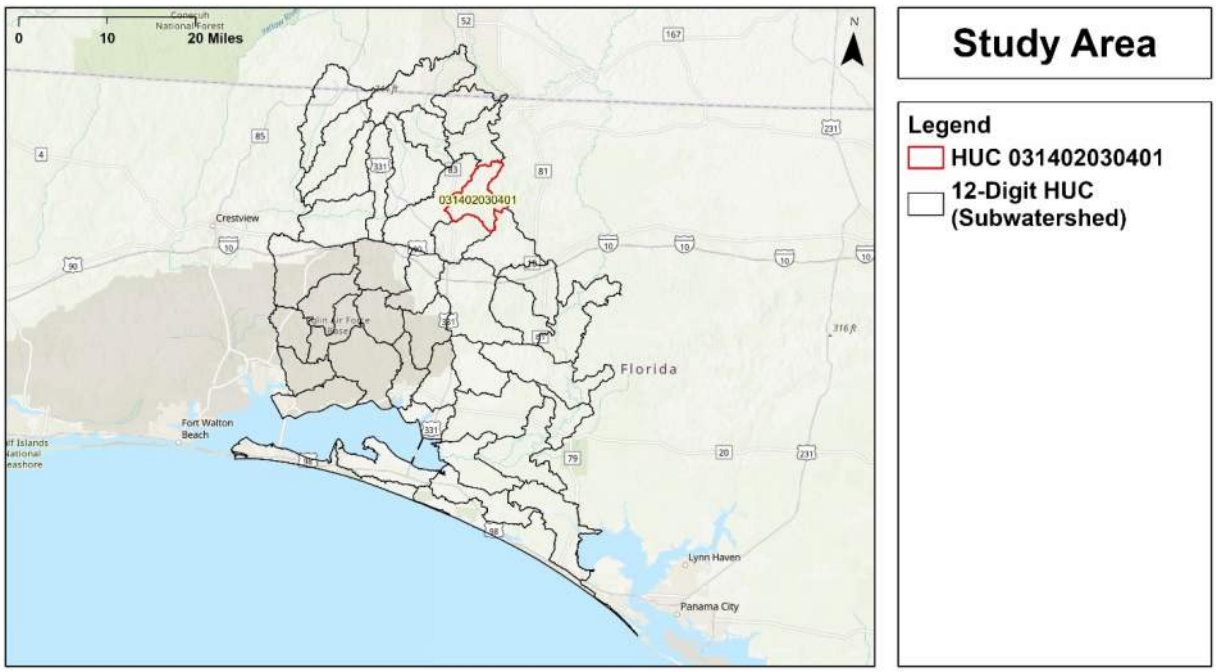

Figure 3. HUC 031402030401 sub-watershed location.

Located in the northwestern region of Florida, Walton County has 1,037.7 square miles of land and it is the 12th largest county in Florida by area, while also sits the highest point in the state, with a height of 345 feet in its northern end. With a population of 75,305 residents according to

the 2020 census and an estimate population in July of 2022 of 83,304, the county has experienced consistent growth within the past several years, driven by factors such as tourism, retirement migration, and regional population dynamics. The county was the residence for 55,043 people according to Census 2010, which leads to a percent change of 36.8% in 10 years, between 2010 and 2020, and a percentage change of 10.6% in two years, between 2020 and 2022 (United States Census Bureau).

The surge in population, particularly in the southern part of Walton County, has resulted in a corresponding expansion of infrastructure to cater to the growing needs. Essential facilities such as potable water systems, wastewater treatment plants, electrical utilities, roads, and schools have been developed to support this increasing population. However, the infrastructure expansion has brought about a significant change in the natural environment. Prior to the existing development , tropical cyclone impacts would be mitigated by natural barriers such as vegetated sand dunes, wetlands, and deserted beaches, which would absorb some of the destructive forces. Now, with the proliferation of costly infrastructure and residential dwellings in coastal areas, these storms pose a higher risk of potential damage. The very areas where development is occurring are becoming more vulnerable to the impact of severe storms, highlighting the importance of considering and implementing adequate measures to address potential storm damage in these coastal regions (Walton County Local Mitigation Strategy Plan, 2015).

Demographically, Walton County presents a heterogeneous age distribution, encompassing a blend of younger and elderly cohorts. The median age of approximately 44 years reflects the presence of both younger families and retirees seeking a serene and picturesque environment. Ethnically, the county' population is predominantly White with smaller yet notable populations of Hispanic/Latino, African American, and other racial/ ethnic groups.

Economically, the tourism sector stands as a dominant force in Walton County, constituting 23.4 percent of the workforce, according to Walton County Economic Development Alliance in 2011, due to its renowned beach destinations, such as Santa Rosa Beach, Miramar Beach, and the New Urbanist Communities of Seaside and Rosemary Beach. Following closely behind is the trade, transportation & utilities sector, accounting for 20.3 percent of employment, while construction stands at 10.0 percent in third place. Education, health care services, and public administration also play significant roles within the top five employment sectors, reflecting the diversified economic landscape of the county (Walton County Local Mitigation Strategy Plan, 2015).

The natural environment in Walton County contributes to its distinctive appeal to visitors and tourists. The county's coastal environment along the Gulf of Mexico showcases picturesque vistas, including white sand beaches, undulating dunes, and coastal dune lakes. These lakes, a rarity worldwide, provide unique ecological habitats. Walton County is also committed to environmental conservation, with designated protected areas comprising state parks, forests, and wildlife management zones. These preserved landscapes offer abundant opportunities for recreational activities, including hiking, fishing, and birdwatching.

The presence of wetlands and waterways further enhances the natural attributes of Walton County. Various rivers and creeks alongside Choctawhatchee Bay permeate the landscape, fostering diverse ecosystems and serving as crucial habitats for a wide range of wildlife species. This rich natural heritage encourages exploration and nurtures an appreciation for the environment.

DeFuniak Springs serves as the county seat and boasts a diverse economy. Anchored by sectors such as healthcare, education, retail, government services, and a thriving small business community, DeFuniak Springs offers a range of employment opportunities. Surrounded by the natural beauty of forests, lakes, and wetlands, the city enjoys the presence of Lake DeFuniak, a noteworthy natural resource. With a population of approximately 5,100 residents, DeFuniak Springs is a vibrant city featuring a mix of economic activities. The land area of DeFuniak Springs is approximately 12.6 square miles (32.7 square kilometers).

Freeport boasts a diverse demographic profile, and a developing economy. The city is situated along the shores of Choctawhatchee Bay, which provides opportunities for recreational opportunities and supports local ecosystems. Surrounded by lush forests and intersected by waterways, Freeport enjoys a rich environmental setting. In terms of economics, Freeport's economy is in a phase of growth and diversification, with sectors including healthcare, education, retail, and small businesses. The city is also strategically positioned for future economic expansion due to its proximity to major transportation corridors. Demographically, Freeport is a close-knit community with a population of approximately 2,600 residents, comprising a mix of permanent residents, retirees, and individuals seeking a suburban or rural lifestyle. The city reflects a diverse demographic composition, showcasing a variety of cultures, and backgrounds. Freeport occupies a land area of about 13.6 square miles (35.3 square kilometers)

Further along the coast, Miramar Beach stands as a coastal gem known for its tourism and hospitality industry. Luxury resorts, vacation rentals, gourmet restaurants, high-end retail shops, and entertainment venues thrive within this bustling city. Miramar Beach's main attraction lies in its stunning white sand beaches along the Gulf of Mexico, providing endless opportunities for beach activities and water sports. Its boundaries extend into neighboring Okaloosa County, attracting a blend of permanent residents, vacation homeowners, and rental property occupants. Miramar Beach, including its neighboring areas, covers an estimated land area of around 4.7 square miles (12.2 square kilometers).

Continuing along the Gulf Coast, we encounter Santa Rosa Beach. This coastal community is renowned for its vibrant tourism industry, offering a plethora of accommodations ranging from upscale resorts to charming vacation rentals. Its demography reflects a mix of permanent residents, seasonal visitors, and individuals seeking a coastal lifestyle, resulting in a diverse and dynamic community. Santa Rosa Beach spans a larger area compared to other cities in Walton County, with an estimated land area of approximately 31.2 square miles (80.8 square kilometers).

A summary of the existing CRS classifications for the communities in the study area is listed in **Error! Reference source not found.**. No cities in Walton County are listed in the FEMA Community Rating System Eligible Communities.

Table 1: Community Rating System for Walton County. Effective April 1, 2023.

Community #	**Community Name**	**CRS Class Rating**	**Premium Discount for SFHA**	**% Discount for Non- SFHA**	**Status**
120317	Walton County	6	20%	10	Cycle

(Source Data: FEMA)

Figures 12 and 13 is the county-wide report show the current and projected land use for the County. Based on the 2017 future land use for Walton County, only 7.07% of the land use in the county is urban and built up, and water/wetlands makes up 29.16% of the land use. The majority of land is upland forest, with 48.3%, as shown in **Error! Reference source not found.**.

Table 2. Land Use in Walton County (Prepared by FAU from future land use map) versus land use in the entire watershed

Level 1 Land Use-Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	52958.94669	7.17%
Barren Land	9242.05986	1.25%
Rangeland	40326.66002	5.46%
Transportation, Communication, and Utilities	11815.69287	1.60%
Upland Forest	356796.0541	48.30%
Urban and Built-Up	52194.79061	7.07%
Water	61593.80508	8.34%
Wetlands	153759.9055	20.82%
Total	**738687.9147**	**100.00%**

(Source Data: NWFWMD, 2017)

Walton County has a history of flooding and has implemented various measures for flooding mitigation over the years (see section 1.12 for more details). The County has experienced flooding primarily due to heavy rainfall events and proximity to large water bodies such as the Gulf of Mexico, Choctawhatchee Bay, and numerous rivers and creeks. The topography of the region, with low-lying areas in the coastal areas and wetlands, also contributes to flood vulnerability. The proximity to the ocean (Gulf of Mexico) makes the county vulnerable to sea level rise. Over the years, Walton County has faced multiple flooding incidents, including:

- March 1997: Heavy rainfall led to significant flooding throughout the county, resulting in property damage and road closures.
- April 2009: Intense storms caused widespread flooding, damaging homes and infrastructure and resulting in the declaration of a state of emergency.
- April 2014: Heavy rainfall caused severe flooding, leading to the evacuation of some residents and the closure of roads.

Today, the goal of a stormwater management system in many communities is to keep the community as a place to live and do business while limiting risk from damage due to flooding. The short-term impacts from stormwater include flooding in low-lying areas and standing water in areas with limited soil storage capacity. Less common, but of increasing frequency, is the potential for extensive inundation of some areas, especially low-lying areas, during periods with high groundwater levels and groundwater impacted by sea level rise. As a result, there is a need to understand the economic impact of flooding events and to create cost-effective stormwater infrastructure and policy solutions to protect property. This means preserving as much property and economic activity as possible without disrupting current activity or expending funds on inappropriate projects with limited long-term or social value.

1.1 Surface Topography

Topography is a key parameter that influences many of the processes involved in flood risk assessment, and thus, up-to-date, high-resolution, high-accuracy elevation data are required. In order to meet the requirements for FEMA Risk Mapping, Assessment, and Planning (RiskMAP), 1-meter (2015 to present) and 1/9 arc-second (~ 3-meter) (2010 -2015) LiDAR DEMs were acquired. The 1 m × 1 m LiDAR tiles were kriged to create a topographic map of the study area (**Error! Reference source not found.**). This accuracy meets the 3DEP Quality Level 2 vertical root mean square error accuracy threshold of ±10 cm for FEMA (Arundel et al., 2015). The LiDAR used for this basin was 2016.

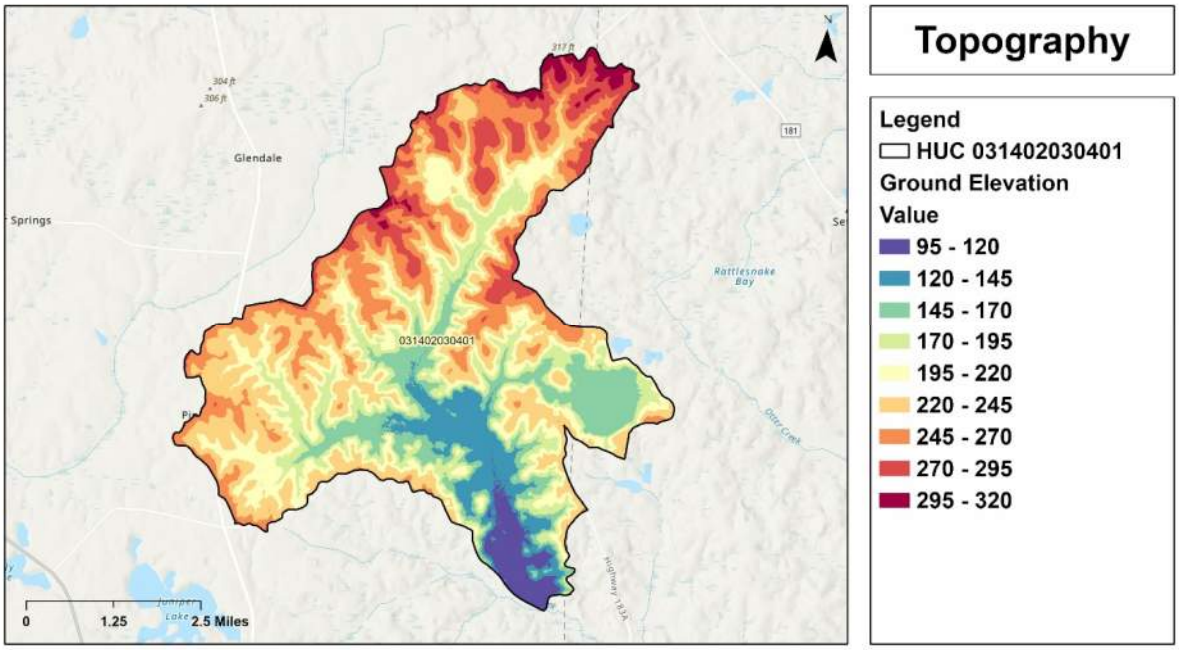

Figure 4. Topographic map of the HUC 031402030401 sub-watershed, processed by FAU

1.1.1 Geomorphological Considerations

Walton County's coastal area is characterized by the presence of barrier islands, extensive sandy beaches, and coastal dune systems. These features are influenced by the dynamic processes of wave action, tidal currents, and wind-driven sediment transport. The shoreline is subject to natural changes, including erosion and accretion, which significantly shape the coastal geomorphology. Inland Walton County exhibits a mix of wetlands, forests, rolling hills, and rivers. These landforms are influenced by a combination of factors, including underlying geology, fluvial processes, and the region's hydrological regime.

Like many areas in Florida, Walton County is underlain by limestone formations. The specific composition and properties of these limestone formations in Walton County may vary. However, limestone is generally known for its porous nature, which allows for the absorption and storage of water. Underground aquifers within the limestone formations can hold significant volumes of freshwater, contributing to the region's water resources.

For context, the FIRM panel index of HUC 031402030401 sub-watershed is shown in **Error! Reference source not found.**.

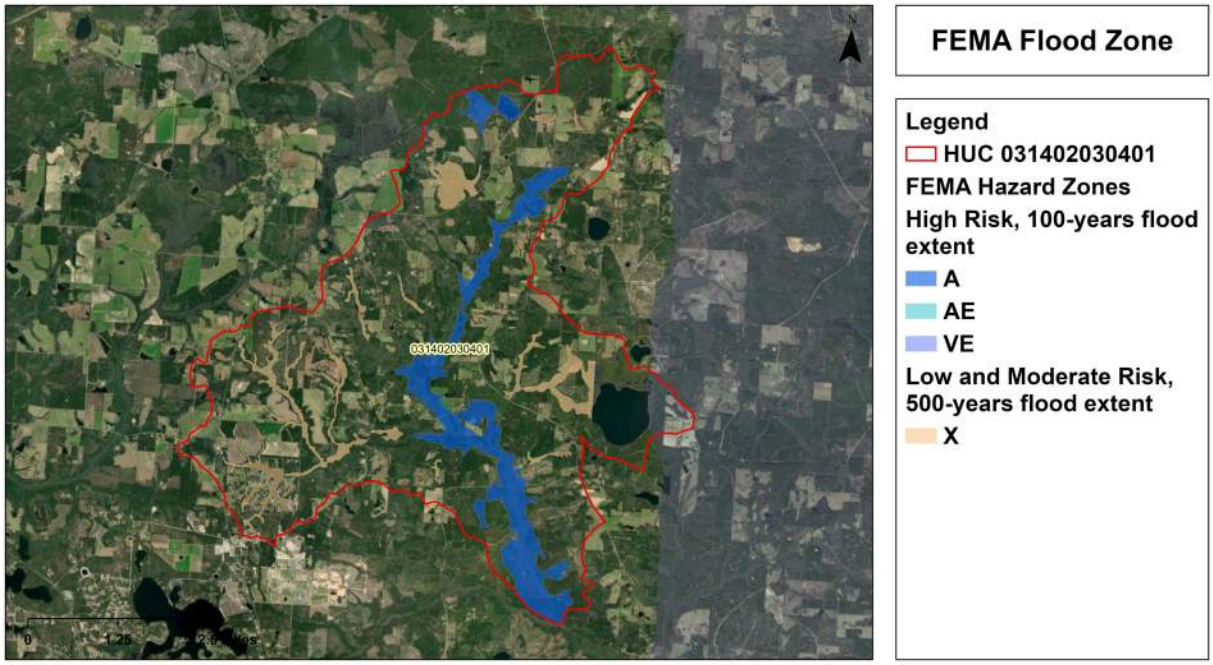

Figure 5. FEMA Flood Zone map (2020) for HUC 031402030401 sub-watershed, processed by FAU.

1.1.2 Waterway Features

In Walton County, Florida, the waterway features are primarily influenced by the presence of rivers, creeks, bayous, and the proximity to the Gulf of Mexico. To the south of Walton County lies the Gulf of Mexico. Sandy beaches, barrier islands, and the open waters of the Gulf itself characterize the coastline along the Gulf. The Gulf of Mexico influences the coastal processes, including wave action, tidal currents, and sediment transport along the shoreline. The combination between sea level rise and King tide would have detrimental consequences for the county costal area, including the sub-watershed 031402030401 as it will reach the area thought Choctawhatchee Bay.

Walton County is home to several rivers and creeks that meander through its landscape. These waterways provide drainage for the inland areas and contribute to the overall hydrological system. Examples of significant rivers in the county include the Choctawhatchee River and the Shoal River. In addition, Walton County features bayous and estuaries that connect inland water systems to the Gulf of Mexico.

Choctawhatchee Bay serves as a vital estuarine ecosystem, where freshwater from rivers and creeks mixes with the saltwater from the Gulf of Mexico, serving as a vital estuarine ecosystem. This unique brackish water environment supports a rich diversity of flora and fauna, including various fish species, shellfish, migratory birds, and wetland vegetation, contributing to the overall biodiversity of the region. It also plays a significant role in the local economy of Walton County as it supports commercial and recreational fishing industries, providing livelihoods for local fishermen and contributing to the seafood industry, while also offering a range of recreational opportunities for residents and visitors alike, such as boating, kayaking, paddle boarding, and sailing. **Error! Reference source not found.** shows the bathymetry offshore.

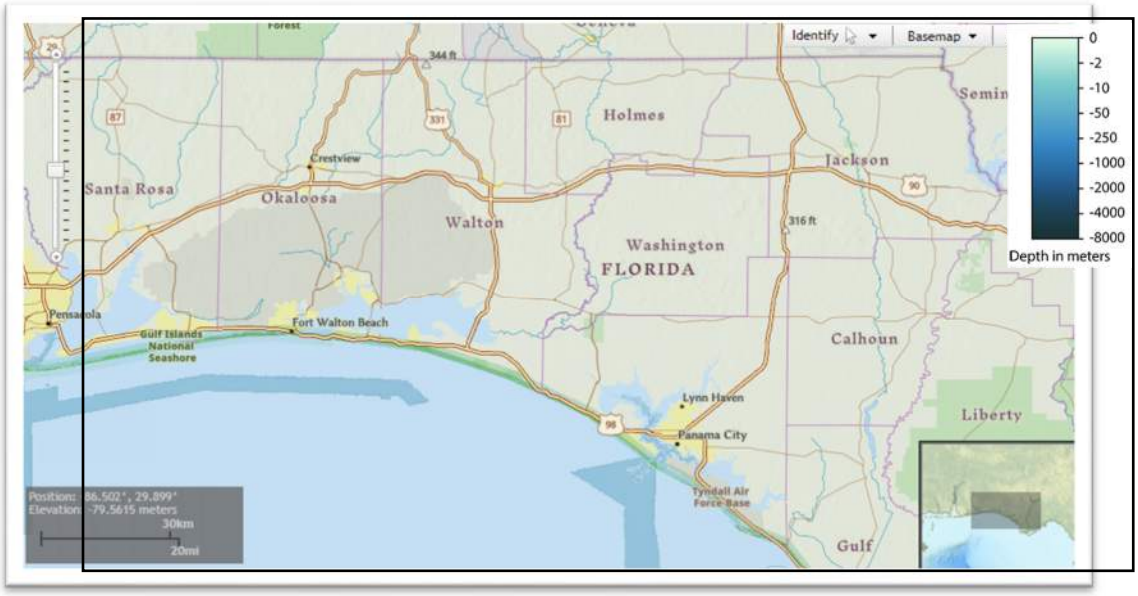

Figure 6. Bathymetry map of the shore of Walton County and surrounding counties of Florida Panhandle.
Source: ncei.noaa.gov/maps/bathymetry/

Numerous tributaries exist throughout both the freshwater and estuarine portions of the watershed and can influence the overall hydrology of the area depending on rainfall and regional hydrological conditions. **Error! Reference source not found.** shows the location of all four surface water stations along with ground water stations (wells) and the drainage network of Walton County.

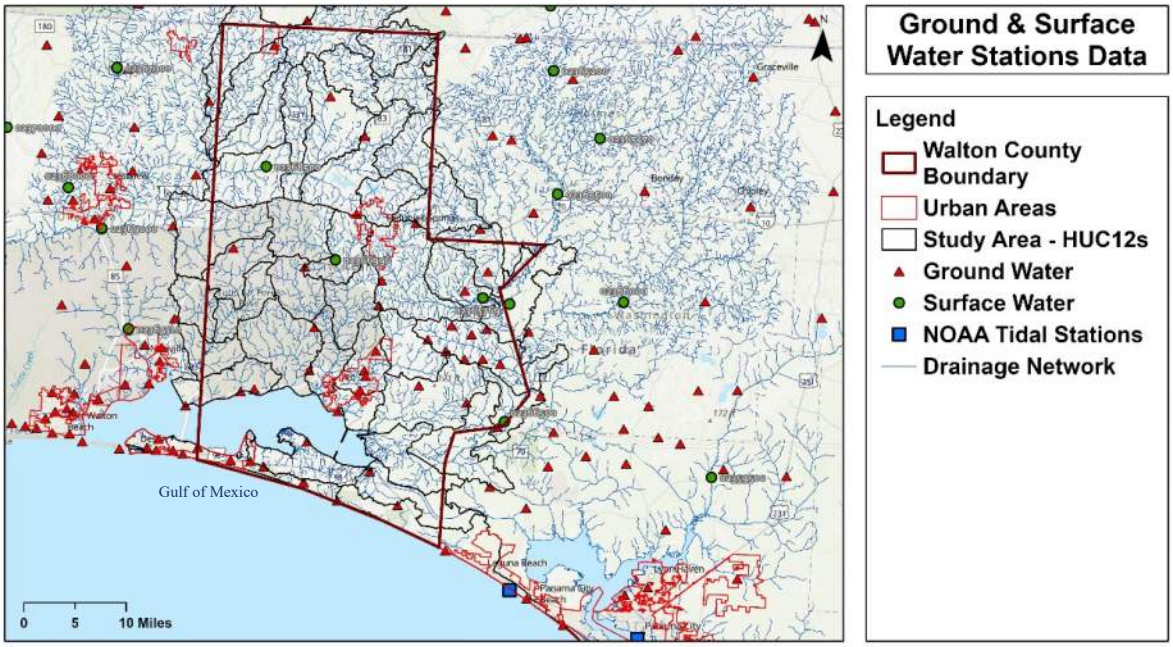

Figure 7. Ground & Surface Water Stations with drainage network for Walton County, processed by FAU.

1.1.3 Hydrologic Boundaries

The geographic area of the subject sub-watershed should be clearly defined to ensure that implementing the WMP will address all the major sources and causes of impairments and threats. Although there is no rigorous definition or delineation of this concept, one way to identify the geographic extent of the watershed master planning effort is to consult the United States Geological Survey (USGS) map of hydrologic units. A hydrologic unit is part of a watershed mapping classification system showing various areas of land that contribute surface water runoff to designated outlet points, such as lakes or stream segments. USGS designates drainage areas as sub-watersheds (including smaller drainages) numbered with 12-digit hydrologic unit codes (HUCs), nested within watersheds (10-digit HUCs). These are combined into larger drainage areas called subbasins (8 digits), basins (6 digits), and subregions (4 digits), which make up the large regional drainage basins (2 digits).

Region>>Subregion>>Basin>>Sub-basin>>Watershed>>Sub-watershed

The HUC 031402030401 has no major rivers and canals, but creeks and branches, which include:

- Sandy Creek
- Anderson Mill Creek

- Camp Creek
- Huckleberry Creek
- Big Branch
- Long Branch
- Bay Branch
- Rattlesnake Branch

Given that stream flow data are critical for estimating flooding, Figure 8 shows the historical streamflow during June 2022 to July 2023 for USGS 02368500. However, as there are only four surface water station within Walton County, it was necessary to use the nearest station to the sub-watershed 031402030401, which is USGS 02368500 Shoal River.

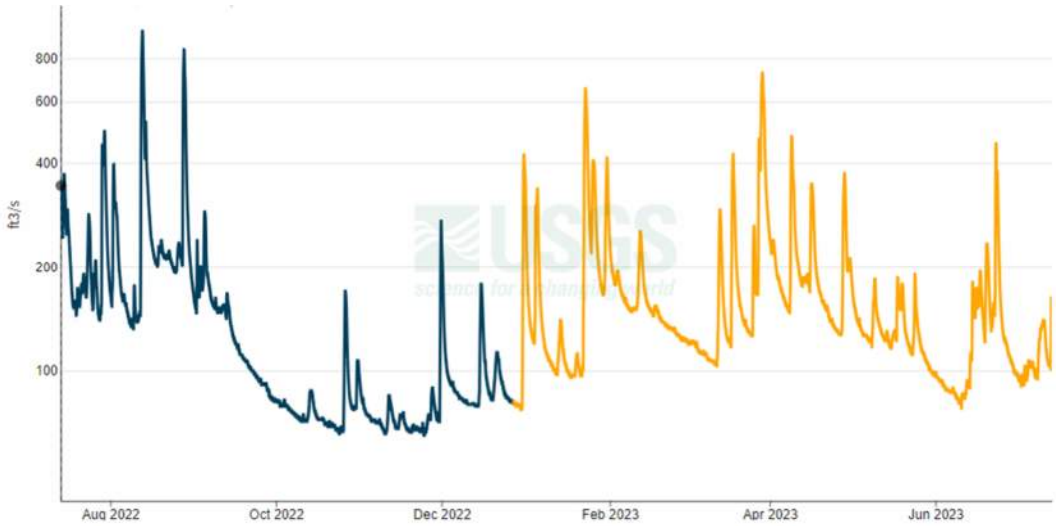

Figure 8. Average streamflow for Shoal River NR Mossy Head, Fla (USGS 02368500 Surface-Water, June 2022 to July 2023).
Source: USGS Water Data Services (https://waterdata.usgs.gov/monitoring-location/02368500/#parameterCode=00065&period=P7D).

1.2 Groundwater

In this region of Florida, there is a direct interaction between groundwater and surface water. In addition to low land elevations and topographic relief, the groundwater and surface water are controlled by the canals, rivers, and tides. Since there is a limited number of groundwater monitoring stations, the strong relationship between groundwater and surface water was leveraged to develop a 99th- percentile surface of the water table elevation for mapping purposes. To establish a common date for modeling, the recorded groundwater table elevations were sorted in ascending order to determine the 98th - 100th percentile date of occurrence in Excel®, following the procedure detailed in Romah (2011). This procedure was automated for this effort using a python code to

process the groundwater data more efficiently. Outliers and anomalous groundwater levels in the database are initially identified (e.g. catastrophic storm events) and replaced by region-specific mean values based on observations available from the nearest well. Missing date-specific data are estimated using simple temporal interpolation based on observations available in time. If a station (or monitoring well) data contains large amounts of missing data, it is not used in the generation of the groundwater surface.

In Walton County, the average annual rainfall is abundant, reaching 65 inches at DeFuniak Springs. This rainfall predominantly infiltrates the sand-and-gravel aquifer and eventually seeps into streams or the underlying artesian Floridan aquifer. The county's two major aquifers are the sand-and-gravel aquifer and the Floridan aquifer. While the sand-and-gravel aquifer provides water for rural domestic use and plays a crucial role in water storage and streamflow maintenance, it also serves as a recharge source for the Floridan aquifer. Water from the sand-and-gravel aquifer contains varying levels of dissolved solids, pH, and iron content. The Floridan aquifer, being the primary water supply source, underlies the entire county and yields around 500 to 1,000 gallons per minute from wells, except along the Gulf Coast where the permeability is lower. Recharged by leakage from the sand-and-gravel aquifer, the Floridan aquifer's movement is predominantly southward away from the potentiometric high in northwestern Walton County. It discharges through springs, seeps along the Choctawhatchee River, and by wells. In southern Alabama, the Floridan aquifer is directly recharged by rainfall when it is exposed or close to the land surface. (Bureau of Ecology, 1974).

Once a common time period is determined across the majority of shallow groundwater wells, canal data can be gathered for that common date (and two days prior, in the event the canals were deliberately lowered). Data was obtained from the NWFWMD and processed by FAU at cwr3.fau.edu. Between stations, an ArcGIS tool permits a line to be drawn to replicate the canals and establish points in a gradient between stations. The same is true for the ocean, but it is a constant head boundary. The canals form boundary conditions for the screening tool on the edges of the basin and affect localized groundwater. The tide issue is resolved by using the common date for high tide.

Error! Reference source not found. shows the drainage network of HUC 031402030401 and points out the location of the ground water station in the surroundings. A groundwater-surface layer for the HUC 031402030401 sub-watershed was created using several datasets including water level data from USGS and NWFWMD and groundwater elevation contour maps. The datasets were used to generate a raster surface of the groundwater elevation (**Error! Reference source not found.**).

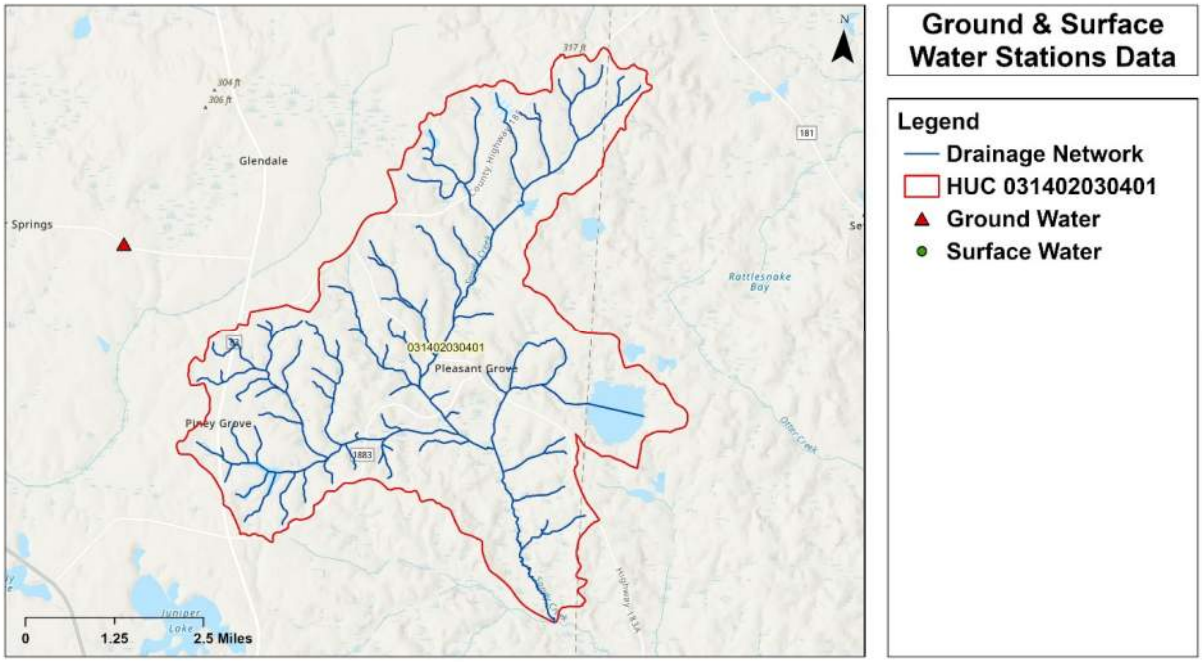

Figure 9. Ground and Surface Water Stations in the HUC 031402030401 sub-watershed, processed by FAU.

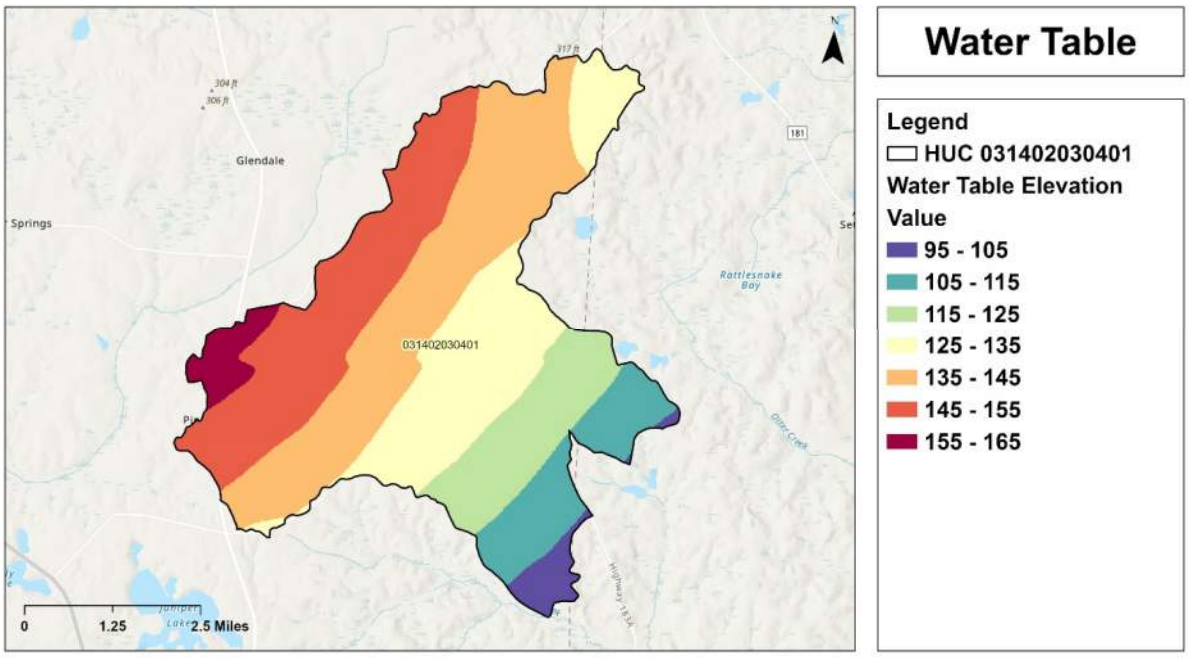

Figure 10. Elevation of the top of the surface groundwater layer for the HUC 031402030401 sub-watershed, created by multiple linear regression analysis – elevation NAVD88, processed by FAU.

Historically, surface water and tides have been an important factor in determining how much freshwater is delivered, how fast this water enters wetlands and estuaries, and the quality of that water. Evapotranspiration and rainfall do not coincide in the study area, which makes water supply planning difficult. **Error! Reference source not found.** shows the average precipitation over Walton County for every month of the year between 2011 and 2023.

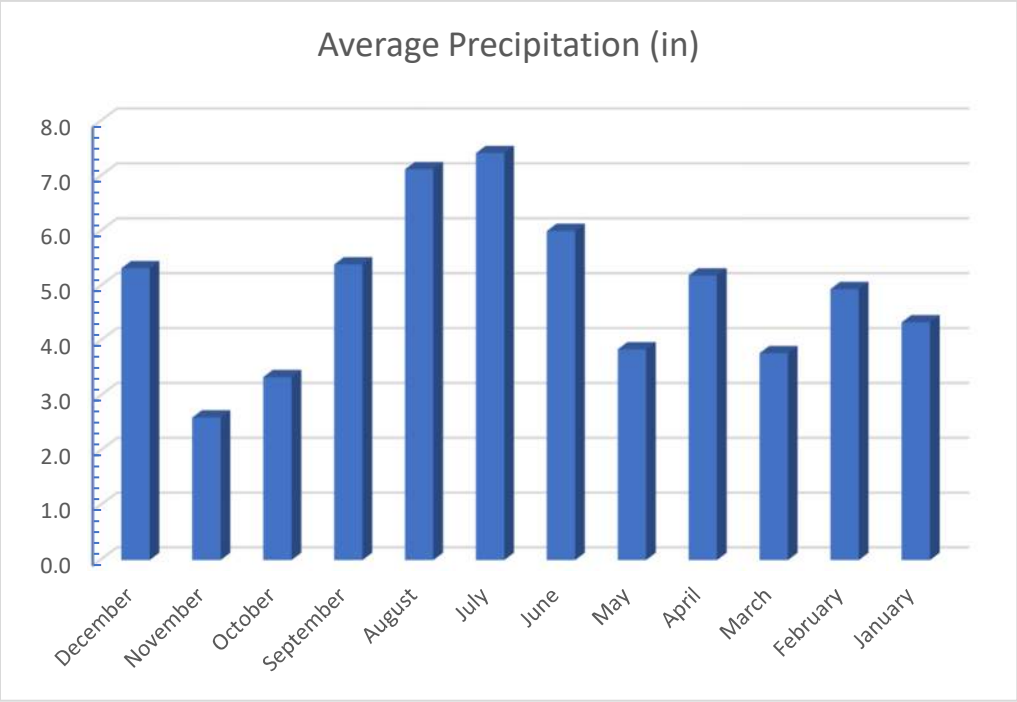

Figure 11. Monthly precipitation in Walton County, FL (2011-2023).
(Data Source: Florida Weather Data, available at https://data.usatoday.com/weather-data/walton-county/12131/1975-04-01/Table/)

While the topography (Section 1.1) and native soil (Section 1.4) create an environment that is highly permeable and capable of infiltrating significant percolation into the soil, changes in land use and land cover have resulted in water falling on impervious areas, where the water collects in pools or runs off rapidly, in direct contrast to the natural condition. This runoff flowing over impermeable regions can lead to larger scale flooding.

Tidal data can be gathered from NOAA tidal gages and other gages monitored by local governments. The location of tide gages is important to ensure they accurately depict tides, as opposed to inland waters. To set a boundary for the coastal areas, the high tide on the common date from 12/03/2018 to 12/10/2018 was selected. **Error! Reference source not found.** shows the two closest tide stations to Walton County. Since there are no NOAA tide station in Walton County, the Panama City Beach station (8729210) was used.

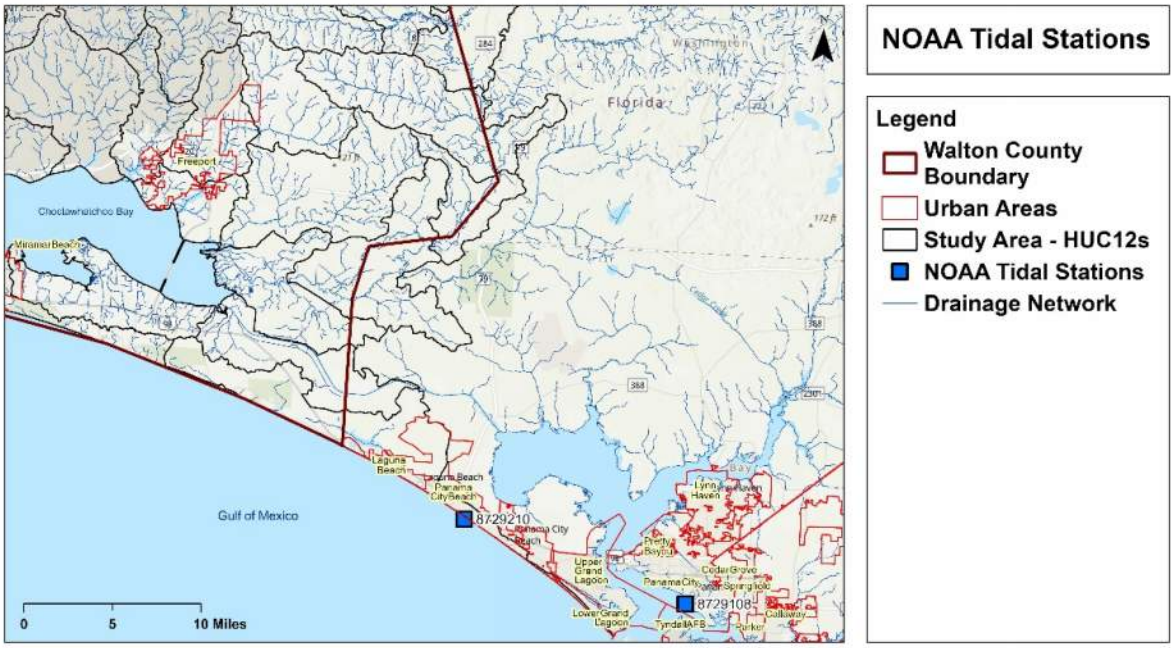

Figure 12. Locations of Florida tidal stations maintained by NOAA near to Walton County, processed by FAU.

1.4 Soils

Soil can store water if there is adequate distance between the topographic surface and the groundwater, and the soil types are capable of absorbing the water. Soil storage capacity is the volume of soil pores in the unsaturated zone that is available to store infiltrated stormwater (Gregory et al., 1998). Throughout Florida, it is common to have large volume storm events that fill the voids in the unsaturated zone as shown in **Error! Reference source not found.**.

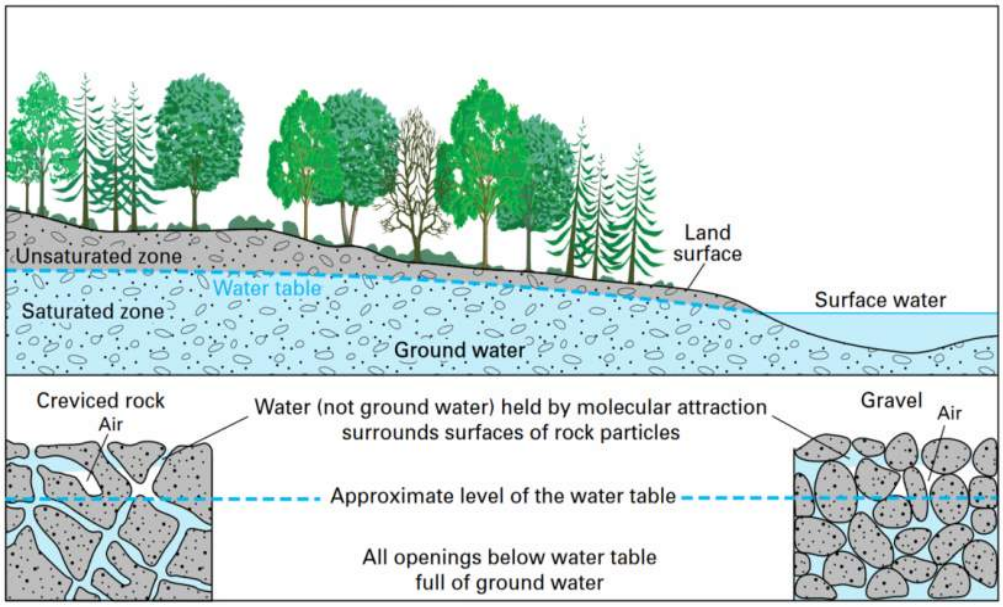

Figure 13. Zones where underground water exists.
Source: USGS, 2020.

The unsaturated zone is the portion of the subsurface above the water table that contains soil/rock and air and water in its pores as shown in **Error! Reference source not found.**. This zone affects the rate at which the aquifer is recharged by controlling water movement from the surface of the land downward towards the aquifer. During rain events, the soil voids fill up quickly resulting in the water table rising to the surface, and the surplus rainfall becomes runoff.

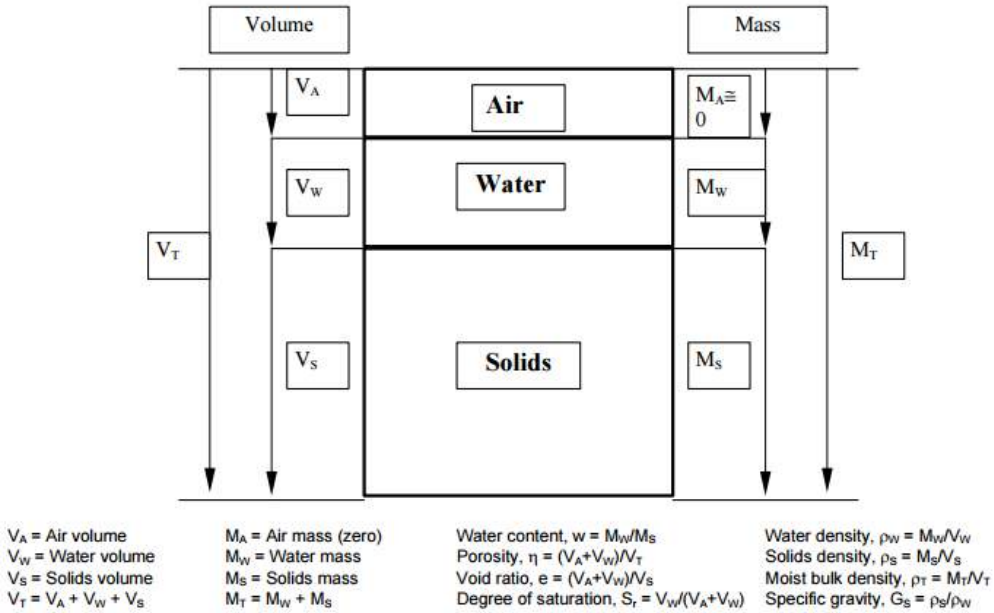

Figure 14. Saturated zone soil phase diagram and definitions.
Source: Gregory et al., 1998.

Soil data is available from the United States Department of Agriculture (USDA) or other agencies in the form of maps that can be incorporated as a GIS layer. The Gridded SSURGO (gSSURGO) dataset from USDA is chosen. This dataset is similar to the standard product from USDA Natural Resources Conservation Service (NRCS) Soil Survey Geographic (SSURGO) database, but is in the Environmental Systems Research Institute, Inc. (ESRI®) file geodatabase format. A file geodatabase allows for statewide or even Conterminous United States (CONUS) tiling of data. The gSSURGO dataset contains all of the original soil attribute tables in SSURGO. All spatial data are stored within the geodatabase instead of externally as separate shape files. Both SSURGO and gSSURGO are considered products of the National Cooperative Soil Survey (NCSS). **Error! Reference source not found.** shows the unsaturated zone found by the difference between the groundwater elevation layer and surface topography.

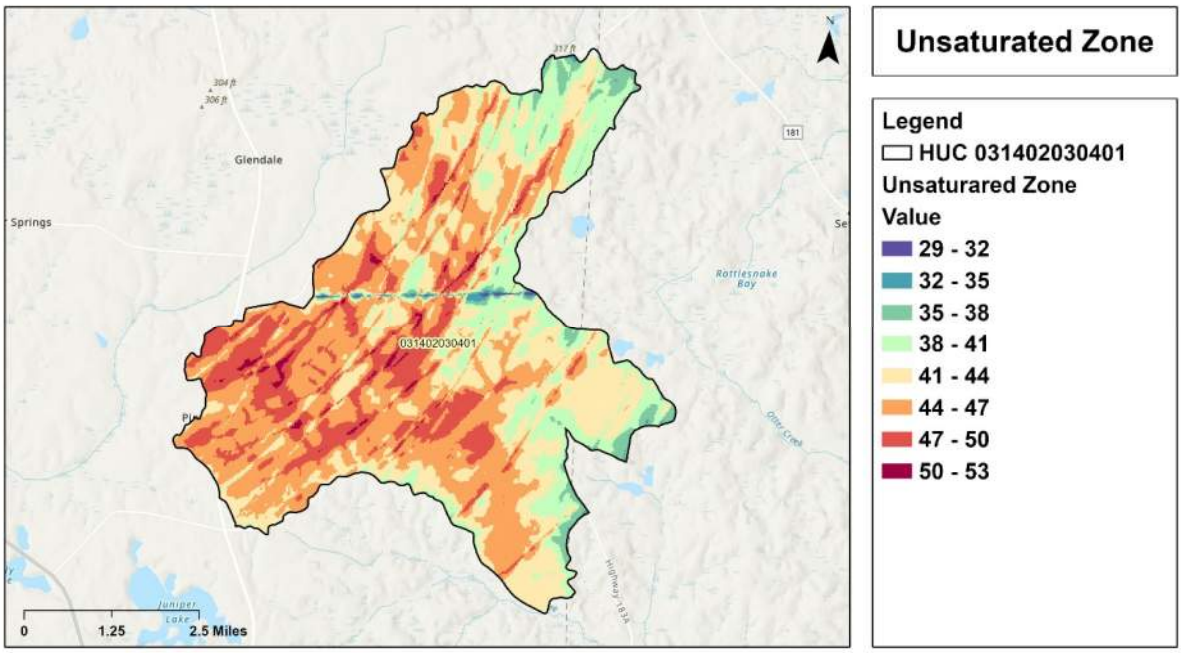

Figure 15. Unsaturated zone map for HUC 031402030401, processed by FAU.

The available water storage from USDA derived for the soil layer (0-150 cm or 0-5 ft) statewide is shown in **Error! Reference source not found.**, which covers most of Florida with a spatial resolution of 10 m. The unit is in cm. As a result of applying this layer to the study area (**Error! Reference source not found.**), the estimated soil storage capacity can be illustrated. A significant portion of the basin exhibits moderately favorable soil storage capacity, ranging between 38 to 50 inches of remaining capacity.

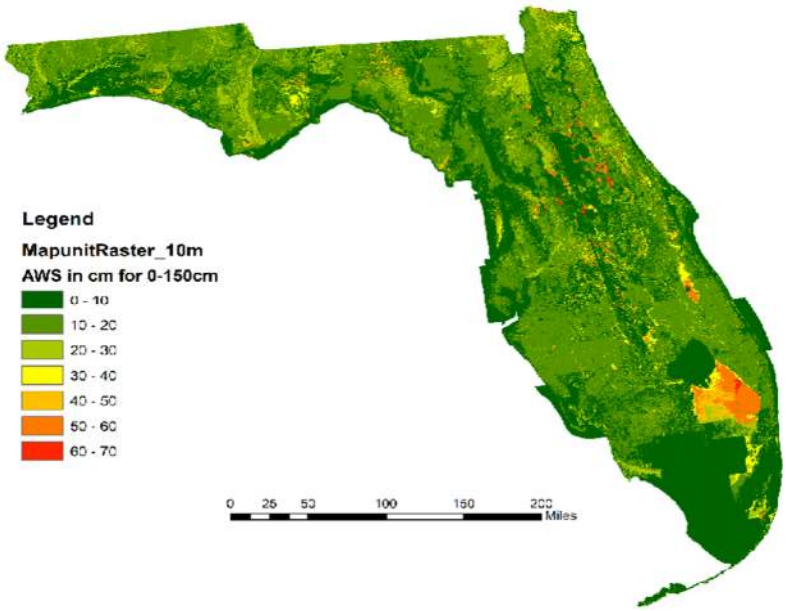

Figure 16. Available water storage derived from the gSSURGO soil database for all of Florida, as processed by FAU.

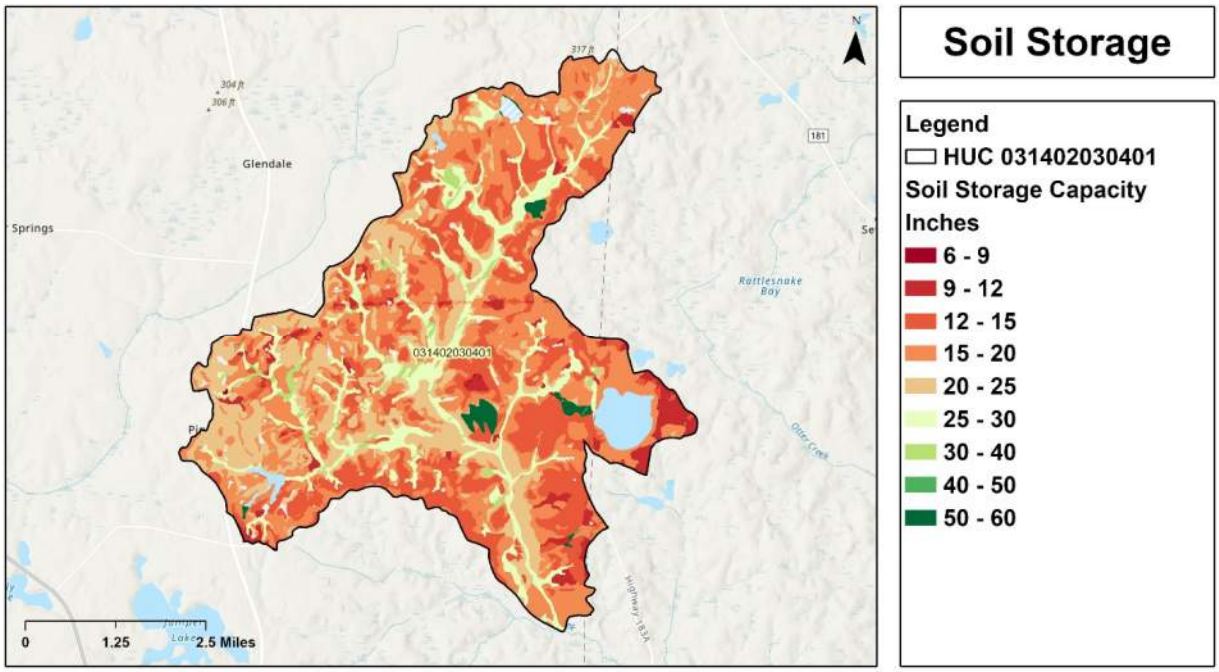

Figure 17. Water storage capacity of soil for the HUC 031402030401, processed by FAU.

Lastly, **Error! Reference source not found.** shows the water holding capacity for the basin, which refers to the capacity of a particular soil texture to retain water against the force of gravity.

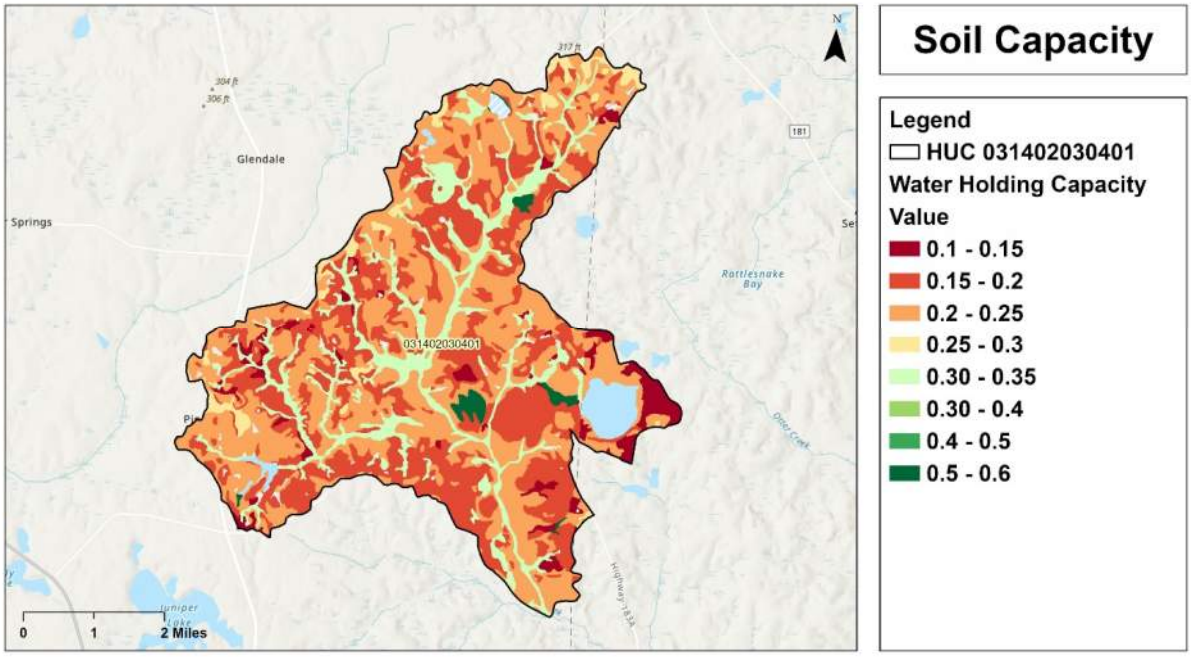

Figure 18. Water Holding Capacity (ratio) for the HUC 031402030401, processed by FAU.

1.5 Land Cover

The USGS produces the NLCD of nationwide data on land cover at a 30-m resolution with a 16-class legend based on a modified Anderson Level II classification system. NLCD is coordinated through the 10-member Multi-Resolution Land Characteristics Consortium (MRLC) to provide digital land cover information nationwide. For the conterminous United States, NLCD 2016 contains 28 different land cover products characterizing land cover and land cover change across 7 epochs from 2001-2016, urban imperviousness and urban imperviousness change across 4 epochs from 2001-2016, tree canopy and tree canopy change across 2 epochs from 2011-2016 and western U.S. shrub and grassland areas for 2016 (**Error! Reference source not found.**).

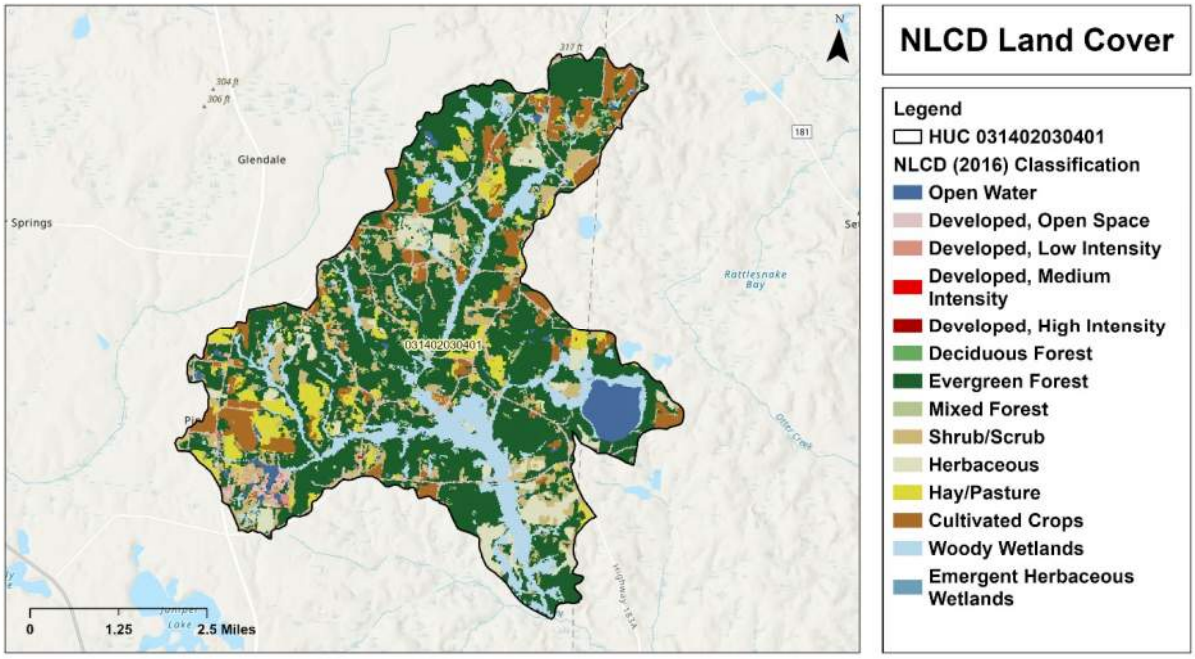

Figure 19. Land use in the HUC 031402030401 (from the NLCD 2016 database), processed by FAU.

The dataset is derived from the Florida Land Use Cover Classification System (FLUCCS), which is digitized by photo-interpretation on county-based aerial photography with varying resolution in the range of 4 in - 2 ft pixel. The NLCD2016 has a 30-meter resolution derived from Landsat imagery. Hence, the NLCD maps appear much coarser and pixelated compared to the 2023 Florida Geographic Data Library (FGDL) (https://fgdl.org/fgdlmap/) maps. A view of the latter is provided in **Error! Reference source not found.**. The future land use maps need to be used for the final land cover, as adjusted for future stormwater improvements set by regulatory standards.

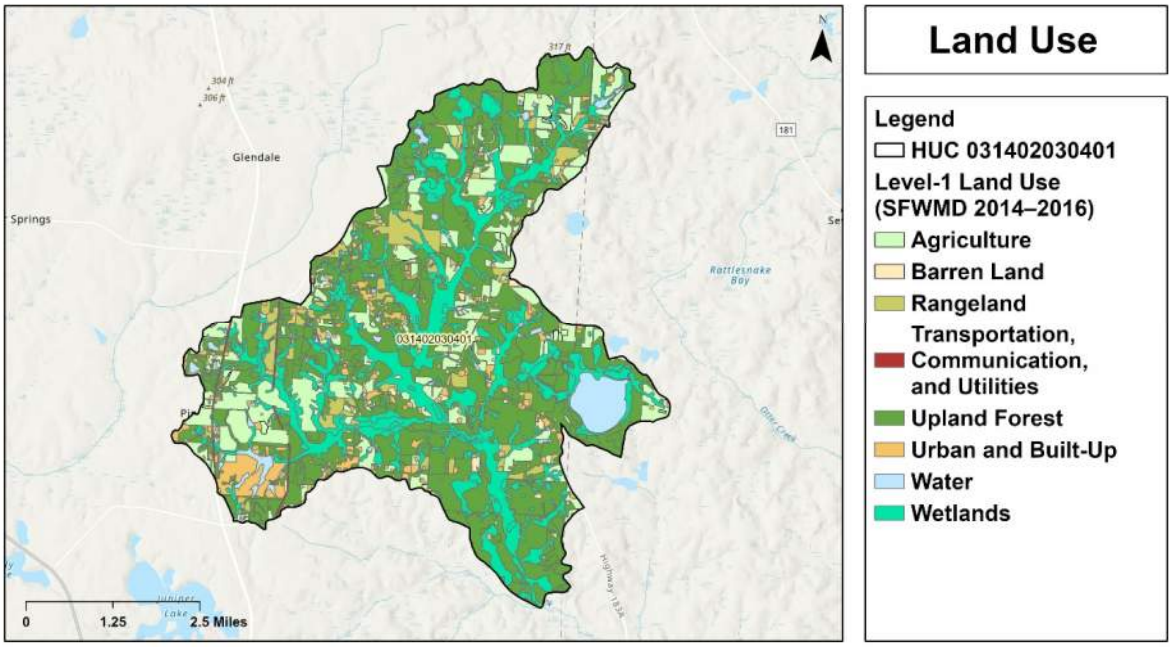

Figure 20. Land use in the HUC 031402030401 (from the 2023 Florida Geographic Data Library (FGDL) database), processed by FAU.

In the HUC 031402030401 sub-watershed, the predominant land cover is upland forest, accounting for 41.85% of the area. Wetlands comes in second at 19.44%, followed by agriculture at 16.15%, and Transportation, Communication, and Utilities at 11.86%. Developed land constitutes a minor portion, with only 4% categorized as urban and built-up, as shown in **Error! Reference source not found.**. **Error! Reference source not found.** shows the roughness of the surface.

Table 3. Land use for HUC 031402030401 subwatershed.

Level 1 Land Use Land Cover Type	**Area (Acres)**	**Percentage of Total**
Agriculture	3857.38	16.15%
Barren Land	63.62	0.27%
Rangeland	921.89	3.86%
Transportation, Communication, and Utilities	2832.22	11.86%
Upland Forest	9994.65	41.85%
Urban and Built-Up	956.15	4.00%
Water	611.62	2.56%
Wetlands	4642.66	19.44%
Grand Total:	**23880.19**	**100.00%**

(Source Data: 2023 Florida Geographic Data Library (FGDL) database))

Table 4. Roughness and CN Values for Each Land Use Code

DOR Code	Use	Impervious %	Roughness
0	Vacant	0	0.4
1	Single Family	29	0.25
2	Mobile homes	21	0.05
4	Condos	60	0.05
7	Vacant –to be developed	0	0.4
8	Multifamily	60	0.05
TH 101	Townhomes	91	0.025
94	Road Right-of-Ways	50	0.08
	Open water	100	n/a
All others	Commercial, etc.	50	0.07

1.6 Precipitation

Rainfall used in the screening tool is based on the SFWMD 3-day 25-year storm, but can be modified for any rainfall event using the accumulated rainfall table obtained from NOAA Atlas 14 Point Precipitation Frequency Estimates (https://hdsc.nws.noaa.gov/hdsc/pfds/pfds_map_cont.html). **Error! Reference source not found.** shows the 3-day 25-year rainfall map based on the NOAA Atlas 14 dataset for the whole state. **Error! Reference source not found.** to **Error! Reference source not found.** rainfall 1-day 100-year, 1-day 10-year, and 1-day 5-year storm event scenarios, in inches.

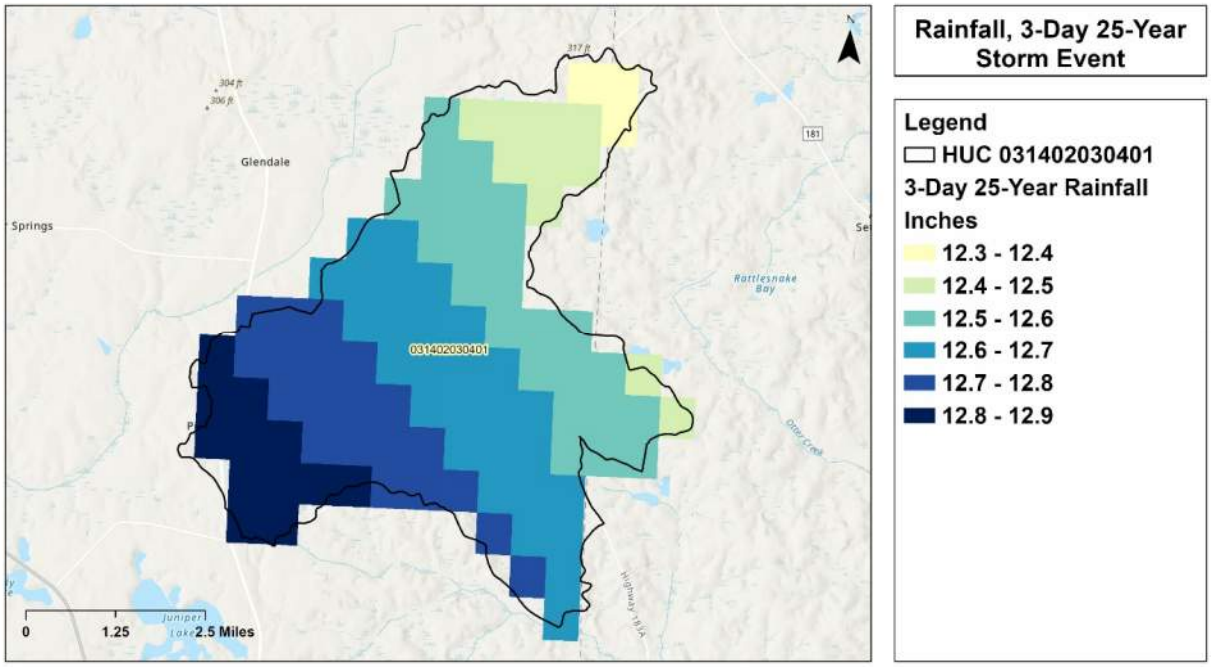

Figure 21. Rainfall distribution map across HUC 031402030401 sub-watershed, for 3-day 25-year storm event, processed by FAU.

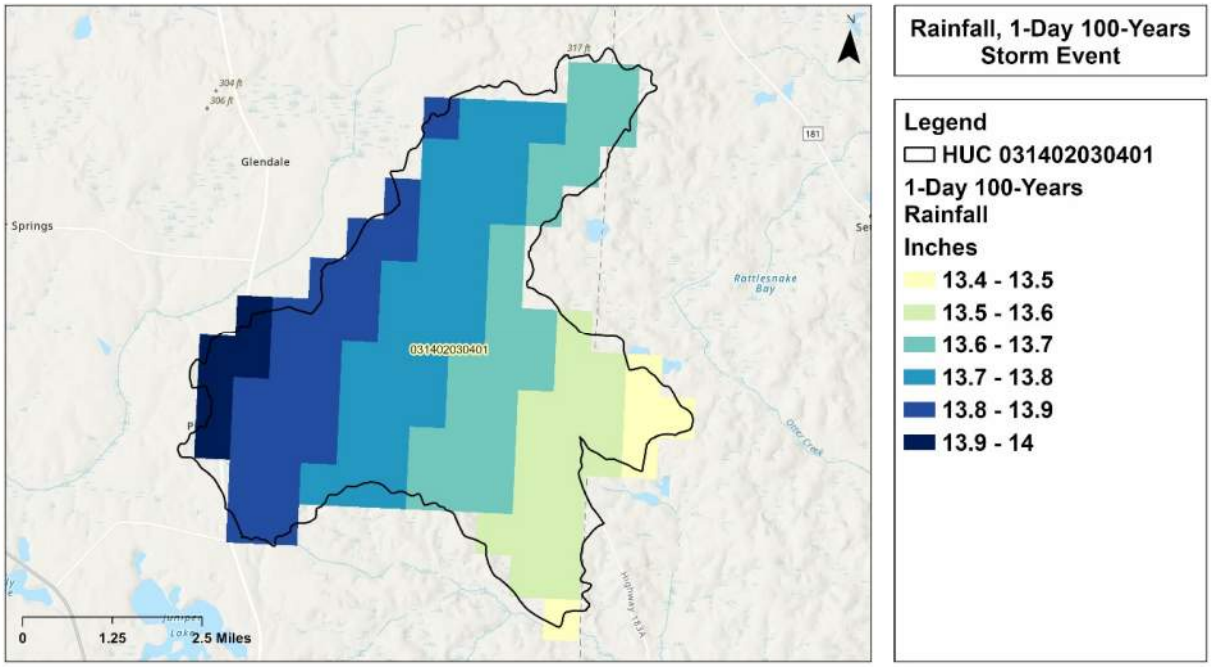

Figure 22. Rainfall distribution map across HUC 031402030401 sub-watershed, for 1-day 100-year storm event, processed by FAU.

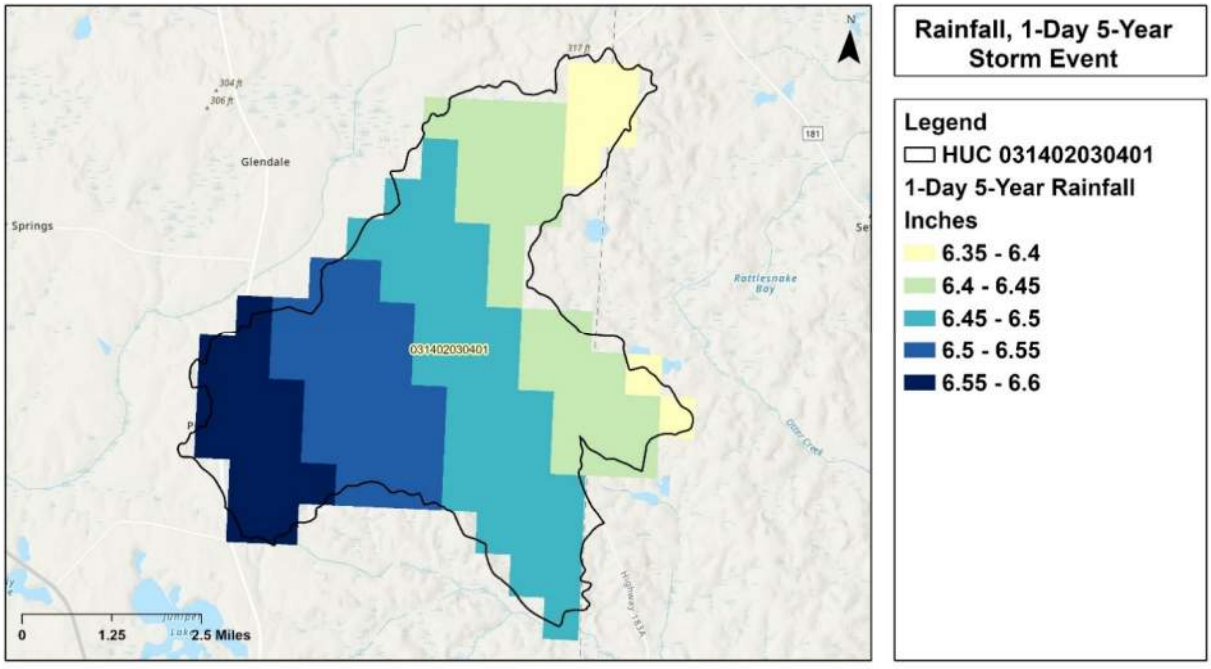

Figure 24. Rainfall distribution map across HUC 031402030401 sub-watershed, for 1-day 5-year storm event, processed by FAU.

1.7 Open Space

Open space is defined as areas that are exempted from development. Generally, this means one or more of the following qualifiers exist:

1. Land that is valuable for recreation, forestry, fishing, or conservation of wildlife or natural resources
2. Land that is a prime natural feature of the state's landscape, such as a shoreline or ridgeline
3. Land that is habitat for native plant or animal species listed as threatened, endangered, or of special concern
4. Land that is a relatively undisturbed example of an uncommon native ecological community
5. Land that is important for enhancing and conserving the water quality of lakes, rivers, and coastal water
6. Land that is valuable for preserving local agricultural heritage
7. Proximity to urban areas or areas with open space deficiencies and underserved populations
8. Vulnerability of land to development
9. Stewardship needs and management constraints
10. Preservation of forest land and water bodies that naturally absorb significant amounts of carbon dioxide

Permanent protection of sensitive areas can provide critical water quality protection and can be achieved through partnerships with landowners, municipalities, land trusts and state agencies. There is limited land in the study area that has been protected via acquisition by federal, state or local agencies, has conservation easements or is designated as wetlands or areas of critical concern. Agricultural land and other land cover will come from the land cover map (in Section 1.5). Added to this will be the water bodies discussed in Section 1.9, which serve a related condition to open space.

1.8 Impervious Areas

Impervious areas do not permit the infiltration of rainfall to groundwater, and because the water cannot infiltrate, it runs off faster. Faster runoff means that flows to water bodies and storm sewers occur faster and with higher peaks. The result is a disruption of the natural and potentially the planned hydrology. Impervious areas include pavement, buildings, and other areas that reduce runoff capacity. In other words, developed areas have much higher imperviousness than open spaces that are natural or agricultural.
